[('red', 1), ('red', 2), ('blue', 1), ('blue', 2)]
```

- The sort routines use `<` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

```
>>> Student.__lt__ = lambda self, other: self.age <
>>> sorted(student_objects)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

However, note that `<` can fall back to using `__gt__()` if `__lt__()` is not implemented (see [object.\\_\\_lt\\_\\_\(\)](#)).

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

```
>>> students = ['dave', 'john', 'jane']
>>> newgrades = {'john': 'F', 'jane': 'A', 'dave': 'C'}
>>> sorted(students, key=newgrades.__getitem__)
['jane', 'dave', 'john']
```

# Unicode HOWTO

## Release

1.12

This HOWTO discusses Python’s support for the Unicode specification for representing textual data, and explains various problems that people commonly encounter when trying to work with Unicode.

## Introduction to Unicode

### Definitions

Today’s programs need to be able to handle a wide variety of characters. Applications are often internationalized to display messages and output in a variety of user-selectable languages; the same program might need to output an error message in English, French, Japanese, Hebrew, or Russian. Web content can be written in any of these languages and can also include a variety of emoji symbols. Python’s string type uses the Unicode Standard for representing characters, which lets Python programs work with all these different possible characters.

Unicode (<https://www.unicode.org/>) is a specification that aims to list every character used by human languages and give each character its own unique code. The Unicode specifications are continually revised and updated to add new languages and symbols.

A **character** is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘È’ and ‘Í’. Characters vary depending on the language or context you’re talking about. For example, there’s a character for “Roman Numeral One”, ‘I’, that’s separate from the uppercase letter ‘I’. They’ll usually look the same, but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point value is an integer in the range 0 to 0x10FFFF (about 1.1 million values, the [actual number assigned](https://www.unicode.org/versions/latest/#Summary) [https://www.unicode.org/versions/latest/#Summary] is less than that). In the standard and in this document, a code point is written using the notation U+265E to mean the character with value 0x265e (9,822 in decimal).

The Unicode standard contains a lot of tables listing characters and their corresponding code points:

```
0061 'a'; LATIN SMALL LETTER A
0062 'b'; LATIN SMALL LETTER B
0063 'c'; LATIN SMALL LETTER C
...
007B '{'; LEFT CURLY BRACKET
...
2167 'VIII'; ROMAN NUMERAL EIGHT
2168 'IX'; ROMAN NUMERAL NINE
...
265E '♞'; BLACK CHESS KNIGHT
265F '♟'; BLACK CHESS PAWN
...
1F600 '😄'; GRINNING FACE
1F609 '😏'; WINKING FACE
...
```

Strictly, these definitions imply that it's meaningless to say 'this is character U+265E'. U+265E is a code point, which represents some particular character; in this case, it represents the character 'BLACK CHESS KNIGHT', '♞'. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn't need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal's font renderer.

## Encodings

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through `0x10FFFF` (1,114,111 decimal). This sequence of code points needs to be represented in memory as a set of **code units**, and **code units** are then mapped to 8-bit bytes. The rules for translating a Unicode string into a sequence of bytes are called a **character encoding**, or just an **encoding**.

The first encoding you might think of is using 32-bit integers as the code unit, and then using the CPU's representation of 32-bit integers. In this representation, the string "Python" might look like this:

P				y					t					h					o
0x50	00	00	00	79	00	00	00	74	00	00	00	68	00	00	00	6f	00		
0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17		

This representation is straightforward but using it presents a number of problems.

1. It's not portable; different processors order the bytes differently.
2. It's very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by `0x00` bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn't matter too much (desktop computers have gigabytes of RAM, and strings aren't usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It's not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.

Therefore this encoding isn't used very much, and people instead choose other encodings that are more efficient and convenient, such as UTF-8.

UTF-8 is one of the most commonly used encodings, and Python

often defaults to using it. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit values are used in the encoding. (There are also UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is  $< 128$ , it’s represented by the corresponding byte value.
2. If the code point is  $\geq 128$ , it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a sequence of bytes that contains embedded zero bytes only where they represent the null character (U+0000). This means that UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes for anything other than end-of-string markers.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.
6. UTF-8 is a byte oriented encoding. The encoding specifies that each character is represented by a specific sequence of one or more bytes. This avoids the byte-ordering issues that can occur with integer and word oriented encodings, like UTF-16 and UTF-32, where the sequence of bytes varies depending on the hardware on which the string was encoded.

## Python's Unicode Support

Now that you've learned the rudiments of Unicode, we can look at Python's Unicode features.

### The String Type

Since Python 3.0, the language's `str` type contains Unicode characters, meaning any string created using `"unicode rocks!"`, `'unicode rocks!'`, or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```
try:
 with open('/tmp/input.txt', 'r') as f:
 ...
```

```
except OSError:
 # 'File not found' error message.
 print("Fichier non trouvé")
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
 f.write("test\n")
```

If you can't enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a u escape.)

```
>>> "\N{GREEK CAPITAL LETTER DELTA}" # Using the character name
'\u0394'
>>> "\u0394" # Using a 16-bit hex escape
'\u0394'
>>> "\U00000394" # Using a 32-bit hex escape
'\u0394'
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an *encoding* argument, such as UTF-8, and optionally an *errors* argument.

The *errors* argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are `'strict'` (raise a `UnicodeDecodeError` exception), `'replace'` (use U+FFFD, REPLACEMENT CHARACTER), `'ignore'` (just leave the character out of the Unicode result), or `'backslashreplace'` (inserts a `\xNN` escape sequence). The following examples show the differences:

```
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
...
UnicodeDecodeError: 'utf-8' codec can't decode byte 0x80:
 invalid start byte
```

```
>>> b'\x80abc'.decode("utf-8", "replace")
'\ufffdabc'
>>> b'\x80abc'.decode("utf-8", "backslashreplace")
'\\x80abc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```

Encodings are specified as strings containing the encoding's name. Python comes with roughly 100 different encodings; see the Python Library Reference at [Standard Encodings](#) for a list. Some encodings have multiple names; for example, 'latin-1', 'iso\_8859\_1' and '8859' are all synonyms for the same encoding.

One-character Unicode strings can also be created with the `chr()` built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in `ord()` function that takes a one-character Unicode string and returns the code point value:

```
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

## Converting to Bytes

The opposite method of `bytes.decode()` is `str.encode()`, which returns a **bytes** representation of the Unicode string, encoded in the requested *encoding*.

The *errors* parameter is the same as the parameter of the `decode()` method but supports a few more possible handlers. As well as 'strict', 'ignore', and 'replace' (which in this case inserts a question mark instead of the unencodable character), there is also 'xmlcharrefreplace' (inserts an XML character reference), 'backslashreplace' (inserts a `\uNNNN` escape sequence) and 'namereplace' (inserts a `\N{...}` escape sequence).

The following example shows the different results:

```

>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
...
UnicodeEncodeError: 'ascii' codec can't encode character
 position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'ꀀabcd޴'
>>> u.encode('ascii', 'backslashreplace')
b'\\ua000abcd\\u07b4'
>>> u.encode('ascii', 'namereplace')
b'\\N{YI SYLLABLE IT}abcd\\u07b4'

```

The low-level routines for registering and accessing the available encodings are found in the [codecs](#) module. Implementing new encodings also requires understanding the [codecs](#) module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won't be covered in this HOWTO.

## Unicode Literals in Python Source Code

In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits giving the code point. The `\U` escape sequence is similar, but expects eight hex digits, not four:

```

>>> s = "a\xac\u1234\u20ac\U00008000"
... # ^^^^ two-digit hex escape
... # ^^^^^ four-digit Unicode escape
... # ^^^^^^^^^ eight-digit Unicode
>>> [ord(c) for c in s]

```

[97, 172, 4660, 8364, 32768]

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you're using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you'd want to be able to write literals in your language's natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
-*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports 'coding'. The `-*-` symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don't include such a comment, the default encoding used will be UTF-8 as already mentioned. See also [PEP 263](https://peps.python.org/pep-0263/) [https://peps.python.org/pep-0263/] for more information.

## Unicode Properties

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character's name, its category, the numeric value if applicable

(for characters representing numeric concepts such as the Roman numerals, fractions such as one-third and four-fifths, etc.). There are also display-related properties, such as how to use the code point in bidirectional text.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) + chr(1000)

for i, c in enumerate(u):
 print(i, '%04x' % ord(c), unicodedata.category(c), end=' ')
 print(unicodedata.name(c))

Get numeric value of second character
print(unicodedata.numeric(u[1]))
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, ‘Ll’ means ‘Letter, lowercase’, ‘No’ means “Number, other”, ‘Mn’ is “Mark, nonspacing”, and ‘So’ is “Symbol, other”. See [the General Category Values section of the Unicode Character Database documentation](https://www.unicode.org/reports/tr44/#General_Category_Values) [https://www.unicode.org/reports/tr44/#General\_Category\_Values] for a list of category codes.

## Comparing Strings

Unicode adds some complication to comparing strings, because the same set of characters can be represented by different sequences of code points. For example, a letter like ‘ê’ can be represented as a single code point U+00EA, or as U+0065 U+0302, which is the code point for ‘e’ followed by a code point for ‘COMBINING CIRCUMFLEX ACCENT’. These will produce the same output when printed, but one is a string of length 1 and the other is of length 2.

One tool for a case-insensitive comparison is the `casefold()` string method that converts a string to a case-insensitive form following an algorithm described by the Unicode Standard. This algorithm has special handling for characters such as the German letter ‘ß’ (code point U+00DF), which becomes the pair of lowercase letters ‘ss’.

```
>>> street = 'Gürzenichstraße'
>>> street.casefold()
'gürzenichstrasse'
```

A second tool is the `unicodedata` module’s `normalize()` function that converts strings to one of several normal forms, where letters followed by a combining character are replaced with single characters. `normalize()` can be used to perform string comparisons that won’t falsely report inequality if two strings use combining characters differently:

```
import unicodedata

def compare_strs(s1, s2):
 def NFD(s):
 return unicodedata.normalize('NFD', s)

 return NFD(s1) == NFD(s2)

single_char = 'ê'
multiple_chars = '\N{LATIN SMALL LETTER E}\N{COMBINING CIRCUMFLEX ACCENT}'
print('length of first string=', len(single_char))
print('length of second string=', len(multiple_chars))
print(compare_strs(single_char, multiple_chars))
```

When run, this outputs:

```
$ python3 compare-strings.py
length of first string= 1
length of second string= 2
True
```

The first argument to the `normalize()` function is a string giving the desired normalization form, which can be one of 'NFC', 'NFKC', 'NFD', and 'NFKD'.

The Unicode Standard also specifies how to do caseless comparisons:

```
import unicodedata

def compare_caseless(s1, s2):
 def NFD(s):
 return unicodedata.normalize('NFD', s)

 return NFD(NFD(s1).casefold()) == NFD(NFD(s2).casefold())

Example usage
single_char = 'ê'
multiple_chars = '\N{LATIN CAPITAL LETTER E}\N{COMBINING DIAERESIS}'

print(compare_caseless(single_char, multiple_chars))
```

This will print `True`. (Why is `NFD()` invoked twice? Because there are a few characters that make `casefold()` return a non-normalized string, so the result needs to be normalized again. See section 3.13 of the Unicode Standard for a discussion and an example.)

## Unicode Regular Expressions

The regular expressions supported by the `re` module can be provided either as bytes or strings. Some of the special character sequences such as `\d` and `\w` have different meanings depending on whether the pattern is supplied as bytes or a string. For example,

`\d` will match the characters `[0-9]` in bytes but in strings will match any character that's in the `'Nd'` category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```
import re
p = re.compile(r'\d+')

s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))
```

When executed, `\d+` will match the Thai numerals and print them out. If you supply the `re.ASCII` flag to `compile()`, `\d+` will match the substring “57” instead.

Similarly, `\w` matches a wide variety of Unicode characters but only `[a-zA-Z0-9_]` in bytes or if `re.ASCII` is supplied, and `\s` will match either Unicode whitespace characters or `[\t\n\r\f\v]`.

EPC2002-Talk.pdf] at EuroPython 2002. The slides are an excellent overview of the design of Python 2's Unicode features (where the Unicode string type is called `unicode` and literals start with `u`).

## Reading and Writing Unicode Data

Once you've written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It's possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It's possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the bytes with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you'd need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()` function can return a file-like object that assumes the file's

contents are in a specified encoding and accepts Unicode parameters for methods such as `read()` and `write()`. This works through `open()`'s *encoding* and *errors* parameters which are interpreted just like those in `str.encode()` and `bytes.decode()`.

Reading Unicode from a file is therefore simple:

```
with open('unicode.txt', encoding='utf-8') as f:
 for line in f:
 print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```
with open('test', encoding='utf-8', mode='w+') as f:
 f.write('\u4500 blah blah blah\n')
 f.seek(0)
 print(repr(f.readline()[:1]))
```

The Unicode character `U+FEFF` is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as 'utf-16-le' and 'utf-16-be' for little-endian and big-endian encodings, that specify one particular byte ordering and don't skip the BOM.

In some areas, it is also convention to use a "BOM" at the start of UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. For reading such files, use the 'utf-8-sig' codec to automatically skip the mark if present.

## Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is

implemented by converting the Unicode string into some encoding that varies depending on the system. Today Python is converging on using UTF-8: Python on MacOS has used UTF-8 for several versions, and Python 3.6 switched to using UTF-8 on Windows as well. On Unix systems, there will only be a [filesystem encoding](#). if you've set the `LANG` or `LC_CTYPE` environment variables; if you haven't, the default encoding is again UTF-8.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there's not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
 f.write('blah\n')
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

The `os.listdir()` function returns filenames, which raises an issue: should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? `os.listdir()` can do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default [filesystem encoding](#) is UTF-8, running the following program:

```
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
$ python listdir-test.py
[b'filename\xe4\x94\x80abc', ...]
['filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, you should can just stick with using Unicode with these APIs. The bytes APIs should only be used on systems where undecodable file names can be present; that's pretty much only Unix systems now.

## Tips for Writing Unicode-aware Programs

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a **`TypeError`** will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you're doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

## Converting Between File Encodings

The `StreamReader` class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file *f* that's in Latin-1, you can wrap it with a `StreamReader` to return bytes encoded in UTF-8:

```
new_f = codecs.StreamReader(f,
 # en/decoder: used by read() to encode its results a
 # by write() to decode its input.
 codecs.getencoder('utf-8'), codecs.getdecoder('utf-8')

 # reader/writer: used to read and write to the stream
 codecs.getreader('latin-1'), codecs.getwriter('latin-1'))
```

## Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don't know the file's encoding? If you know the encoding is ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the `surrogateescape` error handler:

```
with open(fname, 'r', encoding="ascii", errors="surrogateescape") as f:
 data = f.read()

make changes to the string 'data'

with open(fname + '.new', 'w',
 encoding="ascii", errors="surrogateescape") as f:
 f.write(data)
```

The `surrogateescape` error handler will decode any non-ASCII bytes as code points in a special range running from U+DC80 to U+DCFF. These code points will then turn back into the same bytes when the `surrogateescape` error handler is used to encode the data and write it back out.

# HOWTO Fetch Internet Resources Using The urllib Package

Author

[Michael Foord](https://agileabstractions.com/) [https://agileabstractions.com/]

## Note

There is a French translation of an earlier revision of this HOWTO, available at [urllib2 - Le Manuel manquant](https://web.archive.org/web/20200910051922/http://www.voidspace.org.uk/python/articles/urllib2_francais.shtml) [https://web.archive.org/web/20200910051922/http://www.voidspace.org.uk/python/articles/urllib2\_francais.shtml].

## Introduction

### Related Articles

You may also find useful the following article on fetching web resources with Python:

- [Basic Authentication](https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml) [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml]

A tutorial on *Basic Authentication*, with examples in Python.

**urllib.request** is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the *urlopen* function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called

handlers and openers.

`urllib.request` supports fetching URLs for many “URL schemes” (identified by the string before the `:"` in URL - for example `"ftp"` is the URL scheme of `"ftp://python.org/"`) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations *urlopen* is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is [RFC 2616](https://datatracker.ietf.org/doc/html/rfc2616.html) [https://datatracker.ietf.org/doc/html/rfc2616.html]. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using *urllib*, with enough detail about HTTP to help you through. It is not intended to replace the [urllib.request](#) docs, but is supplementary to them.

## Fetching URLs

The simplest way to use `urllib.request` is as follows:

```
import urllib.request
with urllib.request.urlopen('http://python.org/') as response:
 html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the

[`shutil.copyfileobj\(\)`](#) and [`tempfile.NamedTemporaryFile\(\)`](#) functions:

```
import shutil
import tempfile
import urllib.request

with urllib.request.urlopen('http://python.org/') as response:
 with tempfile.NamedTemporaryFile(delete=False) as tmp_file:
 shutil.copyfileobj(response, tmp_file)

with open(tmp_file.name) as html:
```

pass

Many uses of `urllib` will be that simple (note that instead of an ‘http:’ URL we could have used a URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. `urllib.request` mirrors this with a `Request` object which represents the HTTP request you are making. In its simplest form you create a `Request` object that specifies the URL you want to fetch. Calling `urlopen` with this `Request` object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```
import urllib.request

req = urllib.request.Request('http://python.org/')
with urllib.request.urlopen(req) as response:
 the_page = response.read()
```

Note that `urllib.request` makes use of the same `Request` interface to handle all URL schemes. For example, you can make an FTP request like so:

```
req = urllib.request.Request('ftp://example.com/')
```

In the case of HTTP, there are two extra things that `Request` objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information (“metadata”) *about* the data or about the request itself, to the server - this information is sent as HTTP “headers”. Let’s look at each of these in turn.

## Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script or other web application). With HTTP, this is often done using what’s known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs

have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the `data` argument. The encoding is done using a function from the `urllib.parse` library.

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
 'location' : 'Northampton',
 'language' : 'Python' }

data = urllib.parse.urlencode(values)
data = data.encode('ascii') # data should be bytes
req = urllib.request.Request(url, data)
with urllib.request.urlopen(req) as response:
 the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see [HTML Specification, Form Submission](https://www.w3.org/TR/REC-html40/interact/forms.html#h-17.13) [https://www.w3.org/TR/REC-html40/interact/forms.html#h-17.13] for more details).

If you do not pass the `data` argument, `urllib` uses a **GET** request. One way in which GET and POST requests differ is that POST requests often have “side-effects”: they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to *always* cause side-effects, and GET requests *never* to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```
>>> import urllib.request
```

```
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.parse.urlencode(data)
>>> print(url_values) # The order may differ from below
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib.request.urlopen(full_url)
```

Notice that the full URL is created by adding a `?` to the URL, followed by the encoded values.

## Headers

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [1](#) dislike being browsed by programs, or send different versions to different browsers [2](#). By default `urllib` identifies itself as `Python-urllib/x.y` (where `x` and `y` are the major and minor version numbers of the Python release, e.g. `Python-urllib/2.5`), which may confuse the site, or just plain not work. The way a browser identifies itself is through the `User-Agent` header [3](#). When you create a `Request` object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [4](#).

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/5.0 (Windows NT 6.1; Win64; x64)'
values = {'name': 'Michael Foord',
 'location': 'Northampton',
 'language': 'Python' }
headers = {'User-Agent': user_agent}
```

```
data = urllib.parse.urlencode(values)
data = data.encode('ascii')
req = urllib.request.Request(url, data, headers)
with urllib.request.urlopen(req) as response:
 the_page = response.read()
```

The response also has two useful methods. See the section on [info and geturl](#) which comes after we have a look at what happens when things go wrong.

## Handling Exceptions

*urlopen* raises **URLError** when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as **ValueError**, **TypeError** etc. may also be raised).

**HTTPError** is the subclass of **URLError** raised in the specific case of HTTP URLs.

The exception classes are exported from the `urllib.error` module.

### URLError

Often, **URLError** is raised because there is no network connection (no route to the specified server), or the specified server doesn't exist. In this case, the exception raised will have a 'reason' attribute, which is a tuple containing an error code and a text error message.

e.g.

```
>>> req = urllib.request.Request('http://www.pretend_server.com')
>>> try: urllib.request.urlopen(req)
... except urllib.error.URLError as e:
... print(e.reason)
...
(4, 'getaddrinfo failed')
```

## HTTPError

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, `urllib` will handle that for you). For those it can’t handle, `urlopen` will raise an **HTTPError**. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of **RFC 2616** [<https://datatracker.ietf.org/doc/html/rfc2616.html>] for a reference on all the HTTP error codes.

The **HTTPError** instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

### Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100–299 range indicate success, you will usually only see error codes in the 400–599 range.

`http.server.BaseHTTPRequestHandler.responses` is a useful dictionary of response codes in that shows all the response codes used by **RFC 2616** [<https://datatracker.ietf.org/doc/html/rfc2616.html>]. The dictionary is reproduced here for convenience

```
Table mapping response codes to messages; entries have
form {code: (shortmessage, longmessage)}.
responses = {
 100: ('Continue', 'Request received, please continue'),
 101: ('Switching Protocols',
 'Switching to new protocol; obey Upgrade header'),

 200: ('OK', 'Request fulfilled, document follows'),
 201: ('Created', 'Document created, URL follows'),
 202: ('Accepted',
 'Request accepted, processing continues off-line')
}
```

203: ('Non-Authoritative Information', 'Request fulfilled')  
204: ('No Content', 'Request fulfilled, nothing follows')  
205: ('Reset Content', 'Clear input form for further input')  
206: ('Partial Content', 'Partial content follows.')

300: ('Multiple Choices',  
      'Object has several resources -- see URI list'),  
301: ('Moved Permanently', 'Object moved permanently -- see URI list'),  
302: ('Found', 'Object moved temporarily -- see URI list'),  
303: ('See Other', 'Object moved -- see Method and URI location'),  
304: ('Not Modified',  
      'Document has not changed since given time'),  
305: ('Use Proxy',  
      'You must use proxy specified in Location to access the  
      'resource.'),  
307: ('Temporary Redirect',  
      'Object moved temporarily -- see URI list'),

400: ('Bad Request',  
      'Bad request syntax or unsupported method'),  
401: ('Unauthorized',  
      'No permission -- see authorization schemes'),  
402: ('Payment Required',  
      'No payment -- see charging schemes'),  
403: ('Forbidden',  
      'Request forbidden -- authorization will not succeed'),  
404: ('Not Found', 'Nothing matches the given URI'),  
405: ('Method Not Allowed',  
      'Specified method is invalid for this server.'),  
406: ('Not Acceptable', 'URI not available in preferred format'),  
407: ('Proxy Authentication Required', 'You must authenticate  
      this proxy before proceeding.'),  
408: ('Request Timeout', 'Request timed out; try again later'),  
409: ('Conflict', 'Request conflict.'),  
410: ('Gone',  
      'URI no longer exists and has been permanently deleted'),  
411: ('Length Required', 'Client must specify Content-Length'),  
412: ('Precondition Failed', 'Precondition in header is not satisfied')

```

413: ('Request Entity Too Large', 'Entity is too large'),
414: ('Request-URI Too Long', 'URI is too long.'),
415: ('Unsupported Media Type', 'Entity body in unsupported media type'),
416: ('Requested Range Not Satisfiable',
 'Cannot satisfy request range.'),
417: ('Expectation Failed',
 'Expect condition could not be satisfied.'),

500: ('Internal Server Error', 'Server got itself into trouble'),
501: ('Not Implemented',
 'Server does not support this operation'),
502: ('Bad Gateway', 'Invalid responses from another server/proxy'),
503: ('Service Unavailable',
 'The server cannot process the request due to temporary overloading or maintenance of the server'),
504: ('Gateway Timeout',
 'The gateway server did not receive a timely response from the upstream server it was acting as a gateway for.'),
505: ('HTTP Version Not Supported', 'Cannot fulfill request'),
}

```

When an error is raised the server responds by returning an HTTP error code *and* an error page. You can use the **HTTPError** instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the `urllib.response` module:

```

>>> req = urllib.request.Request('http://www.python.org/')
>>> try:
... urllib.request.urlopen(req)
... except urllib.error.HTTPError as e:
... print(e.code)
... print(e.read())
...
404
b'<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
...
<title>Page Not Found</title>\n
...

```

## Wrapping it Up

So if you want to be prepared for **HTTPError** or **URLError** there are two basic approaches. I prefer the second approach.

### Number 1

```
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
 response = urlopen(req)
except HTTPError as e:
 print('The server couldn\'t fulfill the request.')
 print('Error code: ', e.code)
except URLError as e:
 print('We failed to reach a server.')
 print('Reason: ', e.reason)
else:
 # everything is fine
```

### Note

The except **HTTPError** *must* come first, otherwise except **URLError** will *also* catch an **HTTPError**.

### Number 2

```
from urllib.request import Request, urlopen
from urllib.error import URLError
req = Request(someurl)
try:
 response = urlopen(req)
except URLError as e:
 if hasattr(e, 'reason'):
 print('We failed to reach a server.')
 print('Reason: ', e.reason)
 elif hasattr(e, 'code'):
```

```
 print('The server couldn\'t fulfill the request.')
 print('Error code: ', e.code)
else:
 # everything is fine
```

## info and geturl

The response returned by `urlopen` (or the **`HTTPError`** instance) has two useful methods **`info()`** and **`geturl()`** and is defined in the module **`urllib.response`**.

**`geturl`** - this returns the real URL of the page fetched. This is useful because `urlopen` (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

**`info`** - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an **`http.client.HTTPMessage`** instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the [Quick Reference to HTTP Headers](https://jkorpela.fi/http.html) [https://jkorpela.fi/http.html] for a useful listing of HTTP headers with brief explanations of their meaning and use.

## Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly named **`urllib.request.OpenerDirector`**). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle

redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.

## Basic Authentication

To illustrate creating and installing a handler we will use the `HTTPBasicAuthHandler`. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the [Basic Authentication Tutorial](https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml) [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml].

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a 'realm'. The header looks like: `WWW-Authenticate: SCHEME realm="REALM"`.

e.g.

```
WWW-Authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name

and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of `HTTPBasicAuthHandler` and an opener to use this handler.

The `HTTPBasicAuthHandler` uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a `HTTPPasswordMgr`. Frequently one doesn’t care what the realm is. In that case, it is convenient to use `HTTPPasswordMgrWithDefaultRealm`. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing `None` as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to `.add_password()` will also match.

```
create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm()

Add the username and password.
If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username, password)

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

use the opener to fetch a URL
opener.open(a_url)

Install the opener.
Now all calls to urllib.request.urlopen use our opener
urllib.request.install_opener(opener)
```

## Note

In the above example we only supplied our `HTTPBasicAuthHandler` to `build_opener`. By default `openers` have the handlers for normal situations – `ProxyHandler` (if a proxy setting such as an `http_proxy` environment variable is set), `UnknownHandler`, `HTTPHandler`, `HTTPDefaultErrorHandler`, `HTTPRedirectHandler`, `FTPHandler`, `FileHandler`, `DataHandler`, `HTTPErrorProcessor`.

`top_level_url` is in fact *either* a full URL (including the ‘http:’ scheme component and the hostname and optionally the port number) e.g. `"http://example.com/"` or an “authority” (i.e. the hostname, optionally including the port number) e.g. `"example.com"` or `"example.com:8080"` (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component - for example `"joe:password@example.com"` is not correct.

## Proxies

`urllib` will auto-detect your proxy settings and use those. This is through the `ProxyHandler`, which is part of the normal handler chain when a proxy setting is detected. Normally that’s a good thing, but there are occasions when it may not be helpful [5](#). One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a [Basic Authentication](https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml) [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml] handler:

```
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

## Note

Currently `urllib.request` *does not* support fetching of

https locations through a proxy. However, this can be enabled by extending `urllib.request` as shown in the recipe 6.

## Note

`HTTP_PROXY` will be ignored if a variable `REQUEST_METHOD` is set; see the documentation on [getproxies\(\)](#).

# Sockets and Layers

The Python support for fetching resources from the web is layered. `urllib` uses the [http.client](#) library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has *no timeout* and can hang. Currently, the socket timeout is not exposed at the `http.client` or `urllib.request` levels. However, you can set the default timeout globally for all sockets using

```
import socket
import urllib.request

timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

this call to urllib.request.urlopen now uses the default
we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```

---

## Footnotes

This document was reviewed and revised by John Lee.

1

Google for example.

2

Browser sniffing is a very bad practice for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

3

The user agent for MSIE 6 is *'Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)'*

4

For details of more HTTP request headers, see [Quick Reference to HTTP Headers](https://jkorpela.fi/http.html) [https://jkorpela.fi/http.html].

5

In my case I have to use a proxy to access the internet at work. If you attempt to fetch *localhost* URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

urllib opener for SSL proxy (CONNECT method): [ASP.NET Cookbook Recipe](https://code.activestate.com/recipes/456195/) [https://code.activestate.com/recipes/456195/].

# Argparse Tutorial

author

Tshepang Lekhonkhobe

This tutorial is intended to be a gentle introduction to [argparse](#), the recommended command-line parsing module in the Python standard library.

## Note

There are two other modules that fulfill the same task, namely [getopt](#) (an equivalent for `getopt()` from the C language) and the deprecated [optparse](#). Note also that [argparse](#) is based on [optparse](#), and therefore very similar in terms of usage.

## Concepts

Let's show the sort of functionality that we are going to explore in this introductory tutorial by making use of the `ls` command:

```
$ ls
cpython devguide prog.py pypy rm-unused-function.pat
$ ls pypy
ctypes_configure demo dotviewer include lib_pypy li
$ ls -l
total 20
drwxr-xr-x 19 wena wena 4096 Feb 18 18:51 cpython
drwxr-xr-x 4 wena wena 4096 Feb 8 12:04 devguide
-rwxr-xr-x 1 wena wena 535 Feb 19 00:05 prog.py
drwxr-xr-x 14 wena wena 4096 Feb 7 00:59 pypy
-rw-r--r-- 1 wena wena 741 Feb 18 01:01 rm-unused-func
$ ls --help
Usage: ls [OPTION]... [FILE]...
```

```
List information about the FILES (the current directory)
Sort entries alphabetically if none of -cftuvSUX nor --s
...
```

A few concepts we can learn from the four commands:

- The **ls** command is useful when run without any options at all. It defaults to displaying the contents of the current directory.
- If we want beyond what it provides by default, we tell it a bit more. In this case, we want it to display a different directory, `pypy`. What we did is specify what is known as a positional argument. It's named so because the program should know what to do with the value, solely based on where it appears on the command line. This concept is more relevant to a command like **cp**, whose most basic usage is `cp SRC DEST`. The first position is *what you want copied*, and the second position is *where you want it copied to*.
- Now, say we want to change behaviour of the program. In our example, we display more info for each file instead of just showing the file names. The `-l` in that case is known as an optional argument.
- That's a snippet of the help text. It's very useful in that you can come across a program you have never used before, and can figure out how it works simply by reading its help text.

## The basics

Let us start with a very simple example which does (almost) nothing:

```
import argparse
parser = argparse.ArgumentParser()
parser.parse_args()
```

Following is a result of running the code:

```
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h]
```

options:

```
-h, --help show this help message and exit
$ python3 prog.py --verbose
usage: prog.py [-h]
prog.py: error: unrecognized arguments: --verbose
$ python3 prog.py foo
usage: prog.py [-h]
prog.py: error: unrecognized arguments: foo
```

Here is what is happening:

- Running the script without any options results in nothing displayed to stdout. Not so useful.
- The second one starts to display the usefulness of the **argparse** module. We have done almost nothing, but already we get a nice help message.
- The `--help` option, which can also be shortened to `-h`, is the only option we get for free (i.e. no need to specify it). Specifying anything else results in an error. But even then, we do get a useful usage message, also for free.

## Introducing Positional arguments

An example:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo")
args = parser.parse_args()
print(args.echo)
```

And running the code:

```
$ python3 prog.py
usage: prog.py [-h] echo
prog.py: error: the following arguments are required: echo
$ python3 prog.py --help
usage: prog.py [-h] echo
```

```
positional arguments:
 echo
```

```
options:
```

```
-h, --help show this help message and exit
$ python3 prog.py foo
foo
```

Here is what's happening:

- We've added the `add_argument()` method, which is what we use to specify which command-line options the program is willing to accept. In this case, I've named it `echo` so that it's in line with its function.
- Calling our program now requires us to specify an option.
- The `parse_args()` method actually returns some data from the options specified, in this case, `echo`.
- The variable is some form of 'magic' that `argparse` performs for free (i.e. no need to specify which variable that value is stored in). You will also notice that its name matches the string argument given to the method, `echo`.

Note however that, although the help display looks nice and all, it currently is not as helpful as it can be. For example we see that we got `echo` as a positional argument, but we don't know what it does, other than by guessing or by reading the source code. So, let's make it a bit more useful:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo", help="echo the string you use")
args = parser.parse_args()
print(args.echo)
```

And we get:

```
$ python3 prog.py -h
usage: prog.py [-h] echo
```

positional arguments:

echo                    echo the string you use here

options:

-h, --help    show this help message and exit

Now, how about doing something even more useful:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of")
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
Traceback (most recent call last):
 File "prog.py", line 5, in <module>
 print(args.square**2)
TypeError: unsupported operand type(s) for ** or pow():
```

That didn't go so well. That's because **argparse** treats the options we give it as strings, unless we tell it otherwise. So, let's tell **argparse** to treat that input as an integer:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square of",
 type=int)
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
16
$ python3 prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value: 'four'
```

That went well. The program now even helpfully quits on bad illegal input before proceeding.

## Introducing Optional arguments

So far we have been playing with positional arguments. Let us have a look on how to add optional ones:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbosity", help="increase output")
args = parser.parse_args()
if args.verbosity:
 print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbosity 1
verbosity turned on
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h] [--verbosity VERBOSITY]
```

options:

```
-h, --help show this help message and exit
--verbosity VERBOSITY increase output verbosity
```

```
$ python3 prog.py --verbosity
usage: prog.py [-h] [--verbosity VERBOSITY]
prog.py: error: argument --verbosity: expected one argument
```

Here is what is happening:

- The program is written so as to display something when `--verbosity` is specified and display nothing when not.
- To show that the option is actually optional, there is no error when running the program without it. Note that by default, if an optional argument isn't used, the relevant variable, in this case `args.verbosity`, is given `None` as a value, which is

the reason it fails the truth test of the `if` statement.

- The help message is a bit different.
- When using the `--verbosity` option, one must also specify some value, any value.

The above example accepts arbitrary integer values for `--verbosity`, but for our simple program, only two values are actually useful, `True` or `False`. Let's modify the code accordingly:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbose", help="increase output v
 action="store_true")
args = parser.parse_args()
if args.verbose:
 print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbose
verbosity turned on
$ python3 prog.py --verbose 1
usage: prog.py [-h] [--verbose]
prog.py: error: unrecognized arguments: 1
$ python3 prog.py --help
usage: prog.py [-h] [--verbose]
```

options:

```
-h, --help show this help message and exit
--verbose increase output verbosity
```

Here is what is happening:

- The option is now more of a flag than something that requires a value. We even changed the name of the option to match that idea. Note that we now specify a new keyword, `action`, and give it the value `"store_true"`. This means that, if the option is specified, assign the value `True` to `args.verbose`. Not specifying it implies `False`.
- It complains when you specify a value, in true spirit of what

flags actually are.

- Notice the different help text.

## Short options

If you are familiar with command line usage, you will notice that I haven't yet touched on the topic of short versions of the options. It's quite simple:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("-v", "--verbose", help="increase output
 verbosity", action="store_true")
args = parser.parse_args()
if args.verbose:
 print("verbosity turned on")
```

And here goes:

```
$ python3 prog.py -v
verbosity turned on
$ python3 prog.py --help
usage: prog.py [-h] [-v]
```

options:

```
-h, --help show this help message and exit
-v, --verbose increase output verbosity
```

Note that the new ability is also reflected in the help text.

## Combining Positional and Optional arguments

Our program keeps growing in complexity:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
 help="display a square of a given number")
```

```

parser.add_argument("-v", "--verbose", action="store_true",
 help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbose:
 print(f"the square of {args.square} equals {answer}")
else:
 print(answer)

```

And now the output:

```

$ python3 prog.py
usage: prog.py [-h] [-v] square
prog.py: error: the following arguments are required: square
$ python3 prog.py 4
16
$ python3 prog.py 4 --verbose
the square of 4 equals 16
$ python3 prog.py --verbose 4
the square of 4 equals 16

```

- We've brought back a positional argument, hence the complaint.
- Note that the order does not matter.

How about we give this program of ours back the ability to have multiple verbosity values, and actually get to use them:

```

import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
 help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int,
 help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
 print(f"the square of {args.square} equals {answer}")
elif args.verbosity == 1:
 print(f"{args.square}^2 == {answer}")

```

```
else:
 print(answer)
```

And the output:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
usage: prog.py [-h] [-v VERBOSITY] square
prog.py: error: argument -v/--verbosity: expected one ar
$ python3 prog.py 4 -v 1
4^2 == 16
$ python3 prog.py 4 -v 2
the square of 4 equals 16
$ python3 prog.py 4 -v 3
16
```

These all look good except the last one, which exposes a bug in our program. Let's fix it by restricting the values the `--verbosity` option can accept:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
 help="display a square of a given nu
parser.add_argument("-v", "--verbosity", type=int, choice
 help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
 print(f"the square of {args.square} equals {answer}")
elif args.verbosity == 1:
 print(f"{args.square}^2 == {answer}")
else:
 print(answer)
```

And the output:

```
$ python3 prog.py 4 -v 3
usage: prog.py [-h] [-v {0,1,2}] square
```

```
prog.py: error: argument -v/--verbosity: invalid choice:
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v {0,1,2}] square
```

positional arguments:

square	display a square of a given number
--------	------------------------------------

options:

-h, --help	show this help message and exit
-v {0,1,2}, --verbosity {0,1,2}	increase output verbosity

Note that the change also reflects both in the error message as well as the help string.

Now, let's use a different approach of playing with verbosity, which is pretty common. It also matches the way the CPython executable handles its own verbosity argument (check the output of `python --help`):

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
 help="display the square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
 help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
 print(f"the square of {args.square} equals {answer}")
elif args.verbosity == 1:
 print(f"{args.square}^2 == {answer}")
else:
 print(answer)
```

We have introduced another action, “count”, to count the number of occurrences of specific options.

```
$ python3 prog.py 4
16
```

```
$ python3 prog.py 4 -v
4^2 == 16
$ python3 prog.py 4 -vv
the square of 4 equals 16
$ python3 prog.py 4 --verbosity --verbosity
the square of 4 equals 16
$ python3 prog.py 4 -v 1
usage: prog.py [-h] [-v] square
prog.py: error: unrecognized arguments: 1
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v] square
```

positional arguments:

square	display a square of a given number
--------	------------------------------------

options:

-h, --help	show this help message and exit
-v, --verbosity	increase output verbosity

```
$ python3 prog.py 4 -vvv
16
```

- Yes, it's now more of a flag (similar to `action="store_true"`) in the previous version of our script. That should explain the complaint.
- It also behaves similar to “store\_true” action.
- Now here's a demonstration of what the “count” action gives. You've probably seen this sort of usage before.
- And if you don't specify the `-v` flag, that flag is considered to have `None` value.
- As should be expected, specifying the long form of the flag, we should get the same output.
- Sadly, our help output isn't very informative on the new ability our script has acquired, but that can always be fixed by improving the documentation for our script (e.g. via the `help` keyword argument).
- That last output exposes a bug in our program.

Let's fix:

```
import argparse
```

```

args = parser.parse_args()
answer = args.square**2
if args.verbosity >= 2:
 print(f"the square of {args.square} equals {answer}")
elif args.verbosity >= 1:
 print(f"{args.square}^2 == {answer}")
else:
 print(answer)

```

We've just introduced yet another keyword, `default`. We've set it to `0` in order to make it comparable to the other `int` values. Remember that by default, if an optional argument isn't specified, it gets the `None` value, and that cannot be compared to an `int` value (hence the `TypeError` exception).

And:

```

$ python3 prog.py 4
16

```

You can go quite far just with what we've learned so far, and we have only scratched the surface. The `argparse` module is very powerful, and we'll explore a bit more of it before we end this tutorial.

## Getting a little more advanced

What if we wanted to expand our tiny program to perform other powers, not just squares:

```

import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count",
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
 print(f"{args.x} to the power {args.y} equals {answer}")

```

```
elif args.verbosity >= 1:
 print(f"{args.x}^{args.y} == {answer}")
else:
 print(answer)
```

## Output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] x y
prog.py: error: the following arguments are required: x,
$ python3 prog.py -h
usage: prog.py [-h] [-v] x y
```

positional arguments:

x	the base
y	the exponent

options:

-h, --help	show this help message and exit
-v, --verbosity	

```
$ python3 prog.py 4 2 -v
4^2 == 16
```

Notice that so far we've been using verbosity level to *change* the text that gets displayed. The following example instead uses verbosity level to display *more* text instead:

```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count",
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
 print(f"Running '{__file__}'")
if args.verbosity >= 1:
 print(f"{args.x}^{args.y} == ", end="")
print(answer)
```

Output:

```
$ python3 prog.py 4 2
16
$ python3 prog.py 4 2 -v
4^2 == 16
$ python3 prog.py 4 2 -vv
Running 'prog.py'
4^2 == 16
```

## Conflicting options

So far, we have been working with two methods of an `argparse.ArgumentParser` instance. Let's introduce a third one, `add_mutually_exclusive_group()`. It allows for us to specify options that conflict with each other. Let's also change the rest of the program so that the new functionality makes more sense: we'll introduce the `--quiet` option, which will be the opposite of the `--verbose` one:

```
import argparse

parser = argparse.ArgumentParser()
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
 print(answer)
elif args.verbose:
 print(f"{args.x} to the power {args.y} equals {answer}")
else:
 print(f"{args.x}^{args.y} == {answer}")
```

Our program is now simpler, and we've lost some functionality for

the sake of demonstration. Anyways, here's the output:

```
$ python3 prog.py 4 2
4^2 == 16
$ python3 prog.py 4 2 -q
16
$ python3 prog.py 4 2 -v
4 to the power 2 equals 16
$ python3 prog.py 4 2 -vq
usage: prog.py [-h] [-v | -q] x y
prog.py: error: argument -q/--quiet: not allowed with ar
$ python3 prog.py 4 2 -v --quiet
usage: prog.py [-h] [-v | -q] x y
prog.py: error: argument -q/--quiet: not allowed with ar
```

That should be easy to follow. I've added that last output so you can see the sort of flexibility you get, i.e. mixing long form options with short form ones.

Before we conclude, you probably want to tell your users the main purpose of your program, just in case they don't know:

```
import argparse

parser = argparse.ArgumentParser(description="calculate
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
 print(answer)
elif args.verbose:
 print(f"{args.x} to the power {args.y} equals {answer}")
else:
 print(f"{args.x}^{args.y} == {answer}")
```

Note that slight difference in the usage text. Note the `[-v | -q]`, which tells us that we can either use `-v` or `-q`, but not both at the same time:

```
$ python3 prog.py --help
usage: prog.py [-h] [-v | -q] x y
```

calculate X to the power of Y

positional arguments:

x	the base
y	the exponent

options:

-h, --help	show this help message and exit
-v, --verbose	
-q, --quiet	

## Conclusion

The `argparse` module offers a lot more than shown here. Its docs are quite detailed and thorough, and full of examples. Having gone through this tutorial, you should easily digest them without feeling overwhelmed.

# An introduction to the `ipaddress` module

author

Peter Moody

author

Nick Coghlan

## Overview

This document aims to provide a gentle introduction to the `ipaddress` module. It is aimed primarily at users that aren't already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how `ipaddress` represents IP network addressing concepts.

## Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

## A Note on IP Versions

For readers that aren't particularly familiar with IP addressing, it's important to know that the Internet Protocol (IP) is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn't provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

## IP Host Addresses

Addresses, often referred to as “host addresses” are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the `ipaddress.ip_address()` factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:

```
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:DB8::1')
IPv6Address('2001:db8::1')
```

Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address(4254076641128259285690398495165)
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```
>>> ipaddress.ip_address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv4Address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv6Address(1)
IPv6Address('::1')
```

## Defining Networks

Host addresses are usually grouped together into IP networks, so

`ipaddress` provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```
>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
>>> ipaddress.ip_network('2001:db8::0/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in `ValueError` being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```
>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
...
ValueError: 192.0.2.1/24 has host bits set
>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:

```
>>> ipaddress.ip_network(3221225984)
IPv4Network('192.0.2.0/32')
>>> ipaddress.ip_network(4254076641128259285690398495165)
IPv6Network('2001:db8::/128')
```

As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

## Host Interfaces

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like `192.0.2.1/24` is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for “the host `192.0.2.1` on the network `192.0.2.0/24`”, Accordingly, `ipaddress` provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn’t constrained to being a network address.

```
>>> ipaddress.ip_interface('192.0.2.1/24')
IPv4Interface('192.0.2.1/24')
>>> ipaddress.ip_interface('2001:db8::1/96')
IPv6Interface('2001:db8::1/96')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.

## Inspecting Address/Network/Interface Objects

You’ve gone to the trouble of creating an `IPv(4|6)(Address|Network|Interface)` object, so you probably want to get information about it. `ipaddress` tries to make doing this easy and intuitive.

Extracting the IP version:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
256
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.num_addresses
4294967296
```

Iterating through the “usable” addresses on a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
... print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network

prefix) or the hostmask (any bits that are not part of the netmask):

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.netmask
IPv6Address('ffff:ffff:ffff:ffff:ffff:ffff::')
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
>>> net6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0000/96'
>>> net6.compressed
'2001:db8::/96'
```

While IPv4 doesn't support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.

## Networks as lists of Addresses

It's sometimes useful to treat networks as lists. This means it is possible to index them like this:

```
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
```

```
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```
if address in network:
 # do something
```

Containment testing is done efficiently based on the network prefix:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```

## Comparisons

**ipaddress** provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```
>>> ipaddress.ip_address('192.0.2.1') < ipaddress.ip_ad
True
```

A **TypeError** exception is raised if you try to compare objects of different versions or different types.

## Using IP Addresses with other modules

Other modules that use IP addresses (such as **socket**) usually won't accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
```

```
>>> int(addr4)
3221225985
```

## Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as `ValueError` with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it's necessary to know whether the value is *supposed* to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the `ValueError` subclasses `ipaddress.AddressValueError` and `ipaddress.NetmaskValueError` to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```
>>> ipaddress.ip_address("192.168.0.256")
Traceback (most recent call last):
...
ValueError: '192.168.0.256' does not appear to be an IPv4 address
>>> ipaddress.IPv4Address("192.168.0.256")
Traceback (most recent call last):
...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted

>>> ipaddress.ip_network("192.168.0.1/64")
Traceback (most recent call last):
...
ValueError: '192.168.0.1/64' does not appear to be an IPv4 network
>>> ipaddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted
```

```
ipaddress.NetmaskValueError: '64' is not a valid netmask
```

However, both of the module specific exceptions have `ValueError` as their parent class, so if you're not concerned with the particular type of error, you can still write code like the following:

```
try:
 network = ipaddress.IPv4Network(address)
except ValueError:
 print('address/netmask is invalid for IPv4:', address)
```

# Argument Clinic How-To

author

Larry Hastings

## Abstract

Argument Clinic is a preprocessor for CPython C files. Its purpose is to automate all the boilerplate involved with writing argument parsing code for “builtins”. This document shows you how to convert your first C function to work with Argument Clinic, and then introduces some advanced topics on Argument Clinic usage.

Currently Argument Clinic is considered internal-only for CPython. Its use is not supported for files outside CPython, and no guarantees are made regarding backwards compatibility for future versions. In other words: if you maintain an external C extension for CPython, you’re welcome to experiment with Argument Clinic in your own code. But the version of Argument Clinic that ships with the next version of CPython *could* be totally incompatible and break all your code.

## The Goals Of Argument Clinic

Argument Clinic’s primary goal is to take over responsibility for all argument parsing code inside CPython. This means that, when you convert a function to work with Argument Clinic, that function should no longer do any of its own argument parsing—the code generated by Argument Clinic should be a “black box” to you, where CPython calls in at the top, and your code gets called at the bottom, with `PyObject *args` (and maybe `PyObject *kwargs`) magically converted into the C variables and types you need.

In order for Argument Clinic to accomplish its primary goal, it must be easy to use. Currently, working with CPython’s argument parsing library is a chore, requiring maintaining redundant information in a surprising number of places. When you use Argument Clinic, you don’t have to repeat yourself.

Obviously, no one would want to use Argument Clinic unless it’s solving their problem—and without creating new problems of its own. So it’s paramount that Argument Clinic generate correct code. It’d be nice if the code was faster, too, but at the very least it should not introduce a major speed regression. (Eventually Argument Clinic *should* make a major speedup possible—we could rewrite its code generator to produce tailor-made argument parsing code, rather than calling the general-purpose CPython argument parsing library. That would make for the fastest argument parsing possible!)

Additionally, Argument Clinic must be flexible enough to work with any approach to argument parsing. Python has some functions with some very strange parsing behaviors; Argument Clinic’s goal is to support all of them.

Finally, the original motivation for Argument Clinic was to provide introspection “signatures” for CPython builtins. It used to be, the introspection query functions would throw an exception if you passed in a builtin. With Argument Clinic, that’s a thing of the past!

One idea you should keep in mind, as you work with Argument Clinic: the more information you give it, the better job it’ll be able to do. Argument Clinic is admittedly relatively simple right now. But as it evolves it will get more sophisticated, and it should be able to do many interesting and smart things with all the information you give it.

## Basic Concepts And Usage

Argument Clinic ships with CPython; you’ll find it in `Tools/clinic/clinic.py`. If you run that script, specifying a C file as an argument:

```
$ python3 Tools/clinic/clinic.py foo.c
```

Argument Clinic will scan over the file looking for lines that look exactly like this:

```
/*[clinic input]
```

When it finds one, it reads everything up to a line that looks exactly like this:

```
[clinic start generated code]*/
```

Everything in between these two lines is input for Argument Clinic. All of these lines, including the beginning and ending comment lines, are collectively called an Argument Clinic “block”.

When Argument Clinic parses one of these blocks, it generates output. This output is rewritten into the C file immediately after the block, followed by a comment containing a checksum. The Argument Clinic block now looks like this:

```
/*[clinic input]
... clinic input goes here ...
[clinic start generated code]*/
... clinic output goes here ...
/*[clinic end generated code: checksum=...]*/
```

If you run Argument Clinic on the same file a second time, Argument Clinic will discard the old output and write out the new output with a fresh checksum line. However, if the input hasn’t changed, the output won’t change either.

You should never modify the output portion of an Argument Clinic block. Instead, change the input until it produces the output you want. (That’s the purpose of the checksum—to detect if someone changed the output, as these edits would be lost the next time Argument Clinic writes out fresh output.)

For the sake of clarity, here’s the terminology we’ll use with Argument Clinic:

- The first line of the comment (`/*[clinic input]`) is the *start line*.

- The last line of the initial comment (`[clinic start generated code]*/`) is the *end line*.
- The last line (`/*[clinic end generated code: checksum=...]*/`) is the *checksum line*.
- In between the start line and the end line is the *input*.
- In between the end line and the checksum line is the *output*.
- All the text collectively, from the start line to the checksum line inclusively, is the *block*. (A block that hasn't been successfully processed by Argument Clinic yet doesn't have output or a checksum line, but it's still considered a block.)

## Converting Your First Function

The best way to get a sense of how Argument Clinic works is to convert a function to work with it. Here, then, are the bare minimum steps you'd need to follow to convert a function to work with Argument Clinic. Note that for code you plan to check in to CPython, you really should take the conversion farther, using some of the advanced concepts you'll see later on in the document (like “return converters” and “self converters”). But we'll keep it simple for this walkthrough so you can learn.

Let's dive in!

1. Make sure you're working with a freshly updated checkout of the CPython trunk.
2. Find a Python builtin that calls either `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()`, and hasn't been converted to work with Argument Clinic yet. For my example I'm using `_pickle.Pickler.dump()`.
3. If the call to the `PyArg_Parse` function uses any of the following format units:

```
O&
O!
es
es#
```

```
et
et#
```

or if it has multiple calls to `PyArg_ParseTuple()`, you should choose a different function. Argument Clinic *does* support all of these scenarios. But these are advanced topics—let's do something simpler for your first function.

Also, if the function has multiple calls to `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()` where it supports different types for the same argument, or if the function uses something besides `PyArg_Parse` functions to parse its arguments, it probably isn't suitable for conversion to Argument Clinic. Argument Clinic doesn't support generic functions or polymorphic parameters.

4. Add the following boilerplate above the function, creating our block:

```
/*[clinic input]
[clinic start generated code]*/
```

5. Cut the docstring and paste it in between the `[clinic]` lines, removing all the junk that makes it a properly quoted C string. When you're done you should have just the text, based at the left margin, with no line wider than 80 characters. (Argument Clinic will preserve indents inside the docstring.)

If the old docstring had a first line that looked like a function signature, throw that line away. (The docstring doesn't need it anymore—when you use `help()` on your builtin in the future, the first line will be built automatically based on the function's signature.)

Sample:

```
/*[clinic input]
Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

6. If your docstring doesn't have a "summary" line, Argument Clinic will complain. So let's make sure it has one. The "summary" line should be a paragraph consisting of a single 80-column line at the beginning of the docstring.

(Our example docstring consists solely of a summary line, so the sample code doesn't have to change for this step.)

7. Above the docstring, enter the name of the function, followed by a blank line. This should be the Python name of the function, and should be the full dotted path to the function—it should start with the name of the module, include any sub-modules, and if the function is a method on a class it should include the class name too.

Sample:

```
/*[clinic input]
_pickle.Pickler.dump
```

```
Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

8. If this is the first time that module or class has been used with Argument Clinic in this C file, you must declare the module and/or class. Proper Argument Clinic hygiene prefers declaring these in a separate block somewhere near the top of the C file, in the same way that include files and statics go at the top. (In our sample code we'll just show the two blocks next to each other.)

The name of the class and module should be the same as the one seen by Python. Check the name defined in the [PyModuleDef](#) or [PyTypeObject](#) as appropriate.

When you declare a class, you must also specify two aspects of its type in C: the type declaration you'd use for a pointer to an instance of this class, and a pointer to the [PyTypeObject](#) for this class.

Sample:

```

/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

```

```

Write a pickled representation of obj to the open f
[clinic start generated code]*/

```

9. Declare each of the parameters to the function. Each parameter should get its own line. All the parameter lines should be indented from the function name and the docstring.

The general form of these parameter lines is as follows:

```
name_of_parameter: converter
```

If the parameter has a default value, add that after the converter:

```
name_of_parameter: converter = default_value
```

Argument Clinic’s support for “default values” is quite sophisticated; please see [the section below on default values](#) for more information.

Add a blank line below the parameters.

What’s a “converter”? It establishes both the type of the variable used in C, and the method to convert the Python value into a C value at runtime. For now you’re going to use what’s called a “legacy converter”—a convenience syntax intended to make porting old code into Argument Clinic easier.

For each parameter, copy the “format unit” for that parameter from the `PyArg_Parse()` format argument and specify *that* as its converter, as a quoted string. (“format unit” is the formal name for the one-to-three character substring of

the `format` parameter that tells the argument parsing function what the type of the variable is and how to convert it. For more on format units please see [Parsing arguments and building values.](#))

For multicharacter format units like `z#`, use the entire two-or-three character string.

Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_"
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

 obj: 'O'
```

```
Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

10. If your function has `|` in the format string, meaning some parameters have default values, you can ignore it. Argument Clinic infers which parameters are optional based on whether or not they have default values.

If your function has `$` in the format string, meaning it takes keyword-only arguments, specify `*` on a line by itself before the first keyword-only argument, indented the same as the parameter lines.

(`_pickle.Pickler.dump` has neither, so our sample is unchanged.)

11. If the existing C function calls [PyArg\\_ParseTuple\(\)](#) (as opposed to [PyArg\\_ParseTupleAndKeywords\(\)](#)), then all its arguments are positional-only.

To mark all parameters as positional-only in Argument Clinic,

add a `/` on a line by itself after the last parameter, indented the same as the parameter lines.

Currently this is all-or-nothing; either all parameters are positional-only, or none of them are. (In the future Argument Clinic may relax this restriction.)

Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

 obj: 'O'
 /
```

```
Write a pickled representation of obj to the open f
[clinic start generated code]*/
```

12. It's helpful to write a per-parameter docstring for each parameter. But per-parameter docstrings are optional; you can skip this step if you prefer.

Here's how to add a per-parameter docstring. The first line of the per-parameter docstring must be indented further than the parameter definition. The left margin of this first line establishes the left margin for the whole per-parameter docstring; all the text you write will be outdented by this amount. You can write as much text as you like, across multiple lines if you wish.

Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
```

```
[clinic start generated code]*/
```

```
/*[clinic input]
_pickle.Pickler.dump
```

```
 obj: 'O'
 The object to be pickled.
/
```

Write a pickled representation of obj to the open f  
[clinic start generated code]\*/

13. Save and close the file, then run `Tools/clinic/clinic.py` on it. With luck everything worked—your block now has output, and a `.c.h` file has been generated! Reopen the file in your text editor to see:

```
/*[clinic input]
_pickle.Pickler.dump
```

```
 obj: 'O'
 The object to be pickled.
/
```

Write a pickled representation of obj to the open f  
[clinic start generated code]\*/

```
static PyObject *
_pickle_Pickler_dump(PicklerObject *self, PyObject
/*[clinic end generated code: output=87ecad1261e02a
```

Obviously, if Argument Clinic didn't produce any output, it's because it found an error in your input. Keep fixing your errors and retrying until Argument Clinic processes your file without complaint.

For readability, most of the glue code has been generated to a `.c.h` file. You'll need to include that in your original `.c` file, typically right after the clinic module block:

```
#include "clinic/_pickle.c.h"
```

14. Double-check that the argument-parsing code Argument Clinic generated looks basically the same as the existing code.

First, ensure both places use the same argument-parsing function. The existing code must call either

`PyArg_ParseTuple()` or

`PyArg_ParseTupleAndKeywords()`; ensure that the code generated by Argument Clinic calls the *exact* same function.

Second, the format string passed in to

`PyArg_ParseTuple()` or

`PyArg_ParseTupleAndKeywords()` should be *exactly* the same as the hand-written one in the existing function, up to the colon or semi-colon.

(Argument Clinic always generates its format strings with a `:` followed by the name of the function. If the existing code's format string ends with `;`, to provide usage help, this change is harmless—don't worry about it.)

Third, for parameters whose format units require two arguments (like a length variable, or an encoding string, or a pointer to a conversion function), ensure that the second argument is *exactly* the same between the two invocations.

Fourth, inside the output portion of the block you'll find a preprocessor macro defining the appropriate static `PyMethodDef` structure for this builtin:

```
#define __PICKLE_PICKLER_DUMP_METHODDEF \
{"dump", (PyCFunction)__pickle_Pickler_dump, METH_O
```

This static structure should be *exactly* the same as the existing static `PyMethodDef` structure for this builtin.

If any of these items differ in *any* way, adjust your Argument Clinic function specification and rerun `Tools/clinic/clinic.py` until they *are* the same.

15. Notice that the last line of its output is the declaration of your “impl” function. This is where the builtin’s implementation goes. Delete the existing prototype of the function you’re modifying, but leave the opening curly brace. Now delete its argument parsing code and the declarations of all the variables it dumps the arguments into. Notice how the Python arguments are now arguments to this impl function; if the implementation used different names for these variables, fix it.

Let’s reiterate, just because it’s kind of weird. Your code should now look like this:

```
static return_type
your_function_impl(...)
/*[clinic end generated code: checksum=...]*/
{
...

```

Argument Clinic generated the checksum line and the function prototype just above it. You should write the opening (and closing) curly braces for the function, and the implementation inside.

Sample:

```
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler_T
[clinic start generated code]*/
/*[clinic end generated code: checksum=da39a3ee5e6b

/*[clinic input]
_pickle.Pickler.dump

 obj: 'O'
 The object to be pickled.
/

```

Write a pickled representation of obj to the open f

```

[clinic start generated code]*/

PyDoc_STRVAR(__pickle_Pickler_dump__doc__,
"Write a pickled representation of obj to the open
"\n"
...
static PyObject *
_pickle_Pickler_dump_impl(PicklerObject *self, PyOb
/*[clinic end generated code: checksum=3bd30745bf20
{
 /* Check whether the Pickler was initialized co
 Developers often forget to call __init__() i
 would trigger a segfault without this check.
 if (self->write == NULL) {
 PyErr_Format(PicklingError,
 "Pickler.__init__() was not ca
 Py_TYPE(self)->tp_name);
 return NULL;
 }

 if (_Pickler_ClearBuffer(self) < 0)
 return NULL;

 ...

```

16. Remember the macro with the `PyMethodDef` structure for this function? Find the existing `PyMethodDef` structure for this function and replace it with a reference to the macro. (If the builtin is at module scope, this will probably be very near the end of the file; if the builtin is a class method, this will probably be below but relatively near to the implementation.)

Note that the body of the macro contains a trailing comma. So when you replace the existing static `PyMethodDef` structure with the macro, *don't* add a comma to the end.

Sample:

```

static struct PyMethodDef Pickler_methods[] = {
 __PICKLE_PICKLER_DUMP_METHODDEF

```

```

__PICKLE_PICKLER_CLEAR_MEMO_METHODDEF
{NULL, NULL} /* sentinel */
};

```

17. Compile, then run the relevant portions of the regression-test suite. This change should not introduce any new compile-time warnings or errors, and there should be no externally visible change to Python's behavior.

Well, except for one difference: `inspect.signature()` run on your function should now provide a valid signature!

Congratulations, you've ported your first function to work with Argument Clinic!

## Advanced Topics

Now that you've had some experience working with Argument Clinic, it's time for some advanced topics.

### Symbolic default values

The default value you provide for a parameter can't be any arbitrary expression. Currently the following are explicitly supported:

- Numeric constants (integer and float)
- String constants
- `True`, `False`, and `None`
- Simple symbolic constants like `sys.maxsize`, which must start with the name of the module

(In the future, this may need to get even more elaborate, to allow full expressions like `CONSTANT - 1`.)

### Renaming the C functions and variables generated by Argument Clinic

Argument Clinic automatically names the functions it generates for you. Occasionally this may cause a problem, if the generated name

collides with the name of an existing C function. There's an easy solution: override the names used for the C functions. Just add the keyword "as" to your function declaration line, followed by the function name you wish to use. Argument Clinic will use that function name for the base (generated) function, then add "\_impl" to the end and use that for the name of the impl function.

For example, if we wanted to rename the C function names generated for `pickle.Pickler.dump`, it'd look like this:

```
/*[clinic input]
pickle.Pickler.dump as pickler_dumper

...
```

The base function would now be named `pickler_dumper()`, and the impl function would now be named `pickler_dumper_impl()`.

Similarly, you may have a problem where you want to give a parameter a specific Python name, but that name may be inconvenient in C. Argument Clinic allows you to give a parameter different names in Python and in C, using the same "as" syntax:

```
/*[clinic input]
pickle.Pickler.dump

 obj: object
 file as file_obj: object
 protocol: object = NULL
 *
 fix_imports: bool = True
```

Here, the name used in Python (in the signature and the `keywords` array) would be `file`, but the C variable would be named `file_obj`.

You can use this to rename the `self` parameter too!

## Converting functions using `PyArg_UnpackTuple`

To convert a function parsing its arguments with `PyArg_UnpackTuple()`, simply write out all the arguments, specifying each as an `object`. You may specify the `type` argument to cast the type as appropriate. All arguments should be marked positional-only (add a `/` on a line by itself after the last argument).

Currently the generated code will use `PyArg_ParseTuple()`, but this will change soon.

## Optional Groups

Some legacy functions have a tricky approach to parsing their arguments: they count the number of positional arguments, then use a `switch` statement to call one of several different `PyArg_ParseTuple()` calls depending on how many positional arguments there are. (These functions cannot accept keyword-only arguments.) This approach was used to simulate optional arguments back before `PyArg_ParseTupleAndKeywords()` was created.

While functions using this approach can often be converted to use `PyArg_ParseTupleAndKeywords()`, optional arguments, and default values, it's not always possible. Some of these legacy functions have behaviors `PyArg_ParseTupleAndKeywords()` doesn't directly support. The most obvious example is the builtin function `range()`, which has an optional argument on the *left* side of its required argument! Another example is `curses.window.addch()`, which has a group of two arguments that must always be specified together. (The arguments are called `x` and `y`; if you call the function passing in `x`, you must also pass in `y`—and if you don't pass in `x` you may not pass in `y` either.)

In any case, the goal of Argument Clinic is to support argument parsing for all existing CPython builtins without changing their semantics. Therefore Argument Clinic supports this alternate approach to parsing, using what are called *optional groups*. Optional groups are groups of arguments that must all be passed in together. They can be to the left or the right of the required arguments. They can *only* be used with positional-only parameters.

## Note

Optional groups are *only* intended for use when converting functions that make multiple calls to `PyArg_ParseTuple()`! Functions that use *any* other approach for parsing arguments should *almost never* be converted to Argument Clinic using optional groups. Functions using optional groups currently cannot have accurate signatures in Python, because Python just doesn't understand the concept. Please avoid using optional groups wherever possible.

To specify an optional group, add a `[` on a line by itself before the parameters you wish to group together, and a `]` on a line by itself after these parameters. As an example, here's how `curses.window.addch` uses optional groups to make the first two parameters and the last parameter optional:

```
/*[clinic input]

curses.window.addch

 [
 x: int
 X-coordinate.
 y: int
 Y-coordinate.
]

 ch: object
 Character to add.

 [
 attr: long
 Attributes for the character.
]
/

...
```

## Notes:

- For every optional group, one additional parameter will be passed into the `impl` function representing the group. The parameter will be an int named `group_{direction}_{number}`, where `{direction}` is either `right` or `left` depending on whether the group is before or after the required parameters, and `{number}` is a monotonically increasing number (starting at 1) indicating how far away the group is from the required parameters. When the `impl` is called, this parameter will be set to zero if this group was unused, and set to non-zero if this group was used. (By used or unused, I mean whether or not the parameters received arguments in this invocation.)
- If there are no required arguments, the optional groups will behave as if they're to the right of the required arguments.
- In the case of ambiguity, the argument parsing code favors parameters on the left (before the required parameters).
- Optional groups can only contain positional-only parameters.
- Optional groups are *only* intended for legacy code. Please do not use optional groups for new code.

## Using real Argument Clinic converters, instead of “legacy converters”

To save time, and to minimize how much you need to learn to achieve your first port to Argument Clinic, the walkthrough above tells you to use “legacy converters”. “Legacy converters” are a convenience, designed explicitly to make porting existing code to Argument Clinic easier. And to be clear, their use is acceptable when porting code for Python 3.4.

However, in the long term we probably want all our blocks to use Argument Clinic's real syntax for converters. Why? A couple reasons:

- The proper converters are far easier to read and clearer in their intent.
- There are some format units that are unsupported as “legacy converters”, because they require arguments, and the legacy

converter syntax doesn't support specifying arguments.

- In the future we may have a new argument parsing library that isn't restricted to what `PyArg_ParseTuple()` supports; this flexibility won't be available to parameters using legacy converters.

Therefore, if you don't mind a little extra effort, please use the normal converters instead of legacy converters.

In a nutshell, the syntax for Argument Clinic (non-legacy) converters looks like a Python function call. However, if there are no explicit arguments to the function (all functions take their default values), you may omit the parentheses. Thus `bool` and `bool()` are exactly the same converters.

All arguments to Argument Clinic converters are keyword-only. All Argument Clinic converters accept the following arguments:

`c_default`

The default value for this parameter when defined in C. Specifically, this will be the initializer for the variable declared in the “parse function”. See [the section on default values](#) for how to use this. Specified as a string.

`annotation`

The annotation value for this parameter. Not currently supported, because [PEP 8](#) [<https://peps.python.org/pep-0008/>] mandates that the Python library may not use annotations.

In addition, some converters accept additional arguments. Here is a list of these arguments, along with their meanings:

`accept`

A set of Python types (and possibly pseudo-types); this restricts the allowable Python argument to values of these types. (This is not a general-purpose facility; as a rule it only supports specific lists of types as shown

in the legacy converter table.)

To accept `None`, add `NoneType` to this set.

`bitwise`

Only supported for unsigned integers. The native integer value of this Python argument will be written to the parameter without any range checking, even for negative values.

`converter`

Only supported by the `object` converter. Specifies the name of a C “[converter function](#)” to use to convert this object to a native type.

`encoding`

Only supported for strings. Specifies the encoding to use when converting this string from a Python `str` (Unicode) value into a C `char *` value.

`subclass_of`

Only supported for the `object` converter. Requires that the Python value be a subclass of a Python type, as expressed in C.

`type`

Only supported for the `object` and `self` converters. Specifies the C type that will be used to declare the variable. Default value is `"PyObject *"`.

`zeroes`

Only supported for strings. If true, embedded NUL bytes (`'\\0'`) are permitted inside the value. The length of the string will be passed in to the `impl` function, just after the string parameter, as a parameter named `<parameter_name>_length`.

Please note, not every possible combination of arguments will work. Usually these arguments are implemented by specific `PyArg_ParseTuple` *format units*, with specific behavior. For example, currently you cannot call `unsigned_short` without also specifying `bitwise=True`. Although it's perfectly reasonable to think this would work, these semantics don't map to any existing format unit. So Argument Clinic doesn't support it. (Or, at least, not yet.)

Below is a table showing the mapping of legacy converters into real Argument Clinic converters. On the left is the legacy converter, on the right is the text you'd replace it with.

<code>unsigned_char (bitwise=True)</code>	
<code>unsigned_char</code>	
<code>char</code>	
<code>int (accept={str})</code>	
<code>double</code>	
<code>Py_complex</code>	
<code>str(encoding='name_of_encoding')</code>	
<code>str#encoding='name_of_encoding', zeroes=True)</code>	
<code>str(encoding='name_of_encoding', accept={bytes, bytearray, str})</code>	
<code>str#encoding='name_of_encoding', accept={bytes, bytearray, str}, zeroes=True)</code>	
<code>float</code>	
<code>short</code>	
<code>unsigned_short (bitwise=True)</code>	
<code>int</code>	
<code>unsigned_int (bitwise=True)</code>	
<code>unsigned_long (bitwise=True)</code>	
<code>unsigned_long_long (bitwise=True)</code>	
<code>long</code>	
<code>long long</code>	
<code>Py_ssize_t</code>	
<code>object</code>	
<code>object (subclass_of='&amp;PySomething_Type')</code>	
<code>object (converter='name_of_c_function')</code>	
<code>pyl</code>	
<code>PyBytesObject</code>	

<code>\$str</code>
<code>\$str#{zeroes=True}</code>
<code>Pickle*Buffer(accept={buffer, str})</code>
<code>unicode</code>
<code>Pickle*UNICODE</code>
<code>Pickle*UNICODE(zeroes=True)</code>
<code>Pickle*Buffer(accept={rwbuffer})</code>
<code>Pickle*ByteArrayObject</code>
<code>\$str(accept={bytes})</code>
<code>\$str#{accept={robuffer}, zeroes=True}</code>
<code>Pickle*Buffer</code>
<code>Pickle*UNICODE(accept={str, NoneType})</code>
<code>Pickle*UNICODE(accept={str, NoneType}, zeroes=True)</code>
<code>\$str(accept={str, NoneType})</code>
<code>\$str#{accept={str, NoneType}, zeroes=True}</code>
<code>Pickle*Buffer(accept={buffer, str, NoneType})</code>

As an example, here's our sample `pickle.Pickler.dump` using the proper converter:

```
/*[clinic input]
pickle.Pickler.dump

 obj: object
 The object to be pickled.
/
```

Write a pickled representation of `obj` to the open file.  
[clinic start generated code]\*/

One advantage of real converters is that they're more flexible than legacy converters. For example, the `unsigned_int` converter (and all the `unsigned_` converters) can be specified without `bitwise=True`. Their default behavior performs range checking on the value, and they won't accept negative numbers. You just can't do that with a legacy converter!

Argument Clinic will show you all the converters it has available. For each converter it'll show you all the parameters it accepts, along with the default value for each parameter. Just run `Tools/`

`clinic/clinic.py --converters` to see the full list.

## Py\_buffer

When using the `Py_buffer` converter (or the `'s*'`, `'w*'`, `'*y'`, or `'z*'` legacy converters), you *must* not call `PyBuffer_Release()` on the provided buffer. Argument Clinic generates code that does it for you (in the parsing function).

## Advanced converters

Remember those format units you skipped for your first time because they were advanced? Here's how to handle those too.

The trick is, all those format units take arguments—either conversion functions, or types, or strings specifying an encoding. (But “legacy converters” don't support arguments. That's why we skipped them for your first function.) The argument you specified to the format unit is now an argument to the converter; this argument is either `converter` (for `O&`), `subclass_of` (for `O!`), or `encoding` (for all the format units that start with `e`).

When using `subclass_of`, you may also want to use the other custom argument for `object(): type`, which lets you set the type actually used for the parameter. For example, if you want to ensure that the object is a subclass of `PyUnicode_Type`, you probably want to use the converter

```
object (type='PyUnicodeObject *',
 subclass_of='&PyUnicode_Type').
```

One possible problem with using Argument Clinic: it takes away some possible flexibility for the format units starting with `e`. When writing a `PyArg_Parse` call by hand, you could theoretically decide at runtime what encoding string to pass in to `PyArg_ParseTuple()`. But now this string must be hard-coded at Argument-Clinic-preprocessing-time. This limitation is deliberate; it made supporting this format unit much easier, and may allow for future optimizations. This restriction doesn't seem unreasonable; CPython itself always passes in static hard-coded encoding strings for parameters whose format units start with `e`.

## Parameter default values

Default values for parameters can be any of a number of values. At their simplest, they can be string, int, or float literals:

```
foo: str = "abc"
bar: int = 123
bat: float = 45.6
```

They can also use any of Python's built-in constants:

```
yep: bool = True
nope: bool = False
nada: object = None
```

There's also special support for a default value of `NULL`, and for simple expressions, documented in the following sections.

## The `NULL` default value

For string and object parameters, you can set them to `None` to indicate that there's no default. However, that means the C variable will be initialized to `Py_None`. For convenience's sakes, there's a special value called `NULL` for just this reason: from Python's perspective it behaves like a default value of `None`, but the C variable is initialized with `NULL`.

## Expressions specified as default values

The default value for a parameter can be more than just a literal value. It can be an entire expression, using math operators and looking up attributes on objects. However, this support isn't exactly simple, because of some non-obvious semantics.

Consider the following example:

```
foo: Py_ssize_t = sys.maxsize - 1
```

`sys.maxsize` can have different values on different platforms. Therefore Argument Clinic can't simply evaluate that expression

locally and hard-code it in C. So it stores the default in such a way that it will get evaluated at runtime, when the user asks for the function's signature.

What namespace is available when the expression is evaluated? It's evaluated in the context of the module the builtin came from. So, if your module has an attribute called "max\_widgets", you may simply use it:

```
foo: Py_ssize_t = max_widgets
```

If the symbol isn't found in the current module, it fails over to looking in `sys.modules`. That's how it can find `sys.maxsize` for example. (Since you don't know in advance what modules the user will load into their interpreter, it's best to restrict yourself to modules that are preloaded by Python itself.)

Evaluating default values only at runtime means Argument Clinic can't compute the correct equivalent C default value. So you need to tell it explicitly. When you use an expression, you must also specify the equivalent expression in C, using the `c_default` parameter to the converter:

```
foo: Py_ssize_t(c_default="PY_SSIZE_T_MAX - 1") = sys.ma
```

Another complication: Argument Clinic can't know in advance whether or not the expression you supply is valid. It parses it to make sure it looks legal, but it can't *actually* know. You must be very careful when using expressions to specify values that are guaranteed to be valid at runtime!

Finally, because expressions must be representable as static C values, there are many restrictions on legal expressions. Here's a list of Python features you're not permitted to use:

- Function calls.
- Inline if statements (`3 if foo else 5`).
- Automatic sequence unpacking (`*[1, 2, 3]`).
- List/set/dict comprehensions and generator expressions.
- Tuple/list/set/dict literals.

## Using a return converter

By default the `impl` function Argument Clinic generates for you returns `PyObject *`. But your C function often computes some C type, then converts it into the `PyObject *` at the last moment. Argument Clinic handles converting your inputs from Python types into native C types—why not have it convert your return value from a native C type into a Python type too?

That's what a “return converter” does. It changes your `impl` function to return some C type, then adds code to the generated (non-`impl`) function to handle converting that value into the appropriate `PyObject *`.

The syntax for return converters is similar to that of parameter converters. You specify the return converter like it was a return annotation on the function itself. Return converters behave much the same as parameter converters; they take arguments, the arguments are all keyword-only, and if you're not changing any of the default arguments you can omit the parentheses.

(If you use both `"as"` *and* a return converter for your function, the `"as"` should come before the return converter.)

There's one additional complication when using return converters: how do you indicate an error has occurred? Normally, a function returns a valid (non-`NULL`) pointer for success, and `NULL` for failure. But if you use an integer return converter, all integers are valid. How can Argument Clinic detect an error? Its solution: each return converter implicitly looks for a special value that indicates an error. If you return that value, and an error has been set (`PyErr_Occurred()` returns a true value), then the generated code will propagate the error. Otherwise it will encode the value you return like normal.

Currently Argument Clinic supports only a few return converters:

```
bool
int
unsigned int
long
```

```
unsigned int
size_t
Py_ssize_t
float
double
DecodeFSDefault
```

None of these take parameters. For the first three, return -1 to indicate error. For `DecodeFSDefault`, the return type is `const char *`; return a `NULL` pointer to indicate an error.

(There's also an experimental `NoneType` converter, which lets you return `Py_None` on success or `NULL` on failure, without having to increment the reference count on `Py_None`. I'm not sure it adds enough clarity to be worth using.)

To see all the return converters Argument Clinic supports, along with their parameters (if any), just run `Tools/clinic/clinic.py --converters` for the full list.

## Cloning existing functions

If you have a number of functions that look similar, you may be able to use Clinic's "clone" feature. When you clone an existing function, you reuse:

- its parameters, including
  - their names,
  - their converters, with all parameters,
  - their default values,
  - their per-parameter docstrings,
  - their *kind* (whether they're positional only, positional or keyword, or keyword only), and
- its return converter.

The only thing not copied from the original function is its docstring; the syntax allows you to specify a new docstring.

Here's the syntax for cloning a function:

```
/*[clinic input]
```

```
module.class.new_function [as c_basename] = module.class
```

```
Docstring for new_function goes here.
[clinic start generated code]*/
```

(The functions can be in different modules or classes. I wrote `module.class` in the sample just to illustrate that you must use the full path to *both* functions.)

Sorry, there's no syntax for partially cloning a function, or cloning a function then modifying it. Cloning is an all-or nothing proposition.

Also, the function you are cloning from must have been previously defined in the current file.

## Calling Python code

The rest of the advanced topics require you to write Python code which lives inside your C file and modifies Argument Clinic's runtime state. This is simple: you simply define a Python block.

A Python block uses different delimiter lines than an Argument Clinic function block. It looks like this:

```
/*[python input]
python code goes here
[python start generated code]*/
```

All the code inside the Python block is executed at the time it's parsed. All text written to stdout inside the block is redirected into the "output" after the block.

As an example, here's a Python block that adds a static integer variable to the C code:

```
/*[python input]
print('static int __ignored_unused_variable__ = 0;')
[python start generated code]*/
static int __ignored_unused_variable__ = 0;
/*[python checksum:...]*/
```

## Using a “self converter”

Argument Clinic automatically adds a “self” parameter for you using a default converter. It automatically sets the `type` of this parameter to the “pointer to an instance” you specified when you declared the type. However, you can override Argument Clinic’s converter and specify one yourself. Just add your own `self` parameter as the first parameter in a block, and ensure that its converter is an instance of `self_converter` or a subclass thereof.

What’s the point? This lets you override the type of `self`, or give it a different default name.

How do you specify the custom type you want to cast `self` to? If you only have one or two functions with the same type for `self`, you can directly use Argument Clinic’s existing `self` converter, passing in the type you want to use as the `type` parameter:

```
/*[clinic input]
```

```
_pickle.Pickler.dump
```

```
 self: self(type="PicklerObject *")
 obj: object
/
```

```
Write a pickled representation of the given object to th
[clinic start generated code]*/
```

On the other hand, if you have a lot of functions that will use the same type for `self`, it’s best to create your own converter, subclassing `self_converter` but overwriting the `type` member:

```
/*[python input]
```

```
class PicklerObject_converter(self_converter):
 type = "PicklerObject *"
[python start generated code]*/
```

```
/*[clinic input]
```

```
_pickle.Pickler.dump
```

```
self: PicklerObject
obj: object
/
```

Write a pickled representation of the given object to the  
[clinic start generated code]\*/

## Using a “defining class” converter

Argument Clinic facilitates gaining access to the defining class of a method. This is useful for [heap type](#) methods that need to fetch module level state. Use [PyType\\_FromModuleAndSpec\(\)](#) to associate a new heap type with a module. You can now use [PyType\\_GetModuleState\(\)](#) on the defining class to fetch the module state, for example from a module method.

Example from Modules/zlibmodule.c. First, `defining_class` is added to the clinic input:

```
/*[clinic input]
zlib.Compress.compress

 cls: defining_class
 data: Py_buffer
 Binary data to be compressed.
/
```

After running the Argument Clinic tool, the following function signature is generated:

```
/*[clinic start generated code]*/
static PyObject *
zlib_Compress_compress_impl(compobject *self, PyTypeObject
 Py_buffer *data)
/*[clinic end generated code: output=6731b3f0ff357ca6 in
```

The following code can now use

`PyType_GetModuleState(cls)` to fetch the module state:

```
zlibstate *state = PyType_GetModuleState(cls);
```

Each method may only have one argument using this converter, and it must appear after `self`, or, if `self` is not used, as the first argument. The argument will be of type `PyTypeObject *`. The argument will not appear in the `__text_signature__`.

The `defining_class` converter is not compatible with `__init__` and `__new__` methods, which cannot use the `METH_METHOD` convention.

It is not possible to use `defining_class` with slot methods. In order to fetch the module state from such methods, use `PyType_GetModuleByDef()` to look up the module and then `PyModule_GetState()` to fetch the module state. Example from the `setattro` slot method in `Modules/_threadmodule.c`:

```
static int
local_setattro(localobject *self, PyObject *name, PyObject
{
 PyObject *module = PyType_GetModuleByDef(Py_TYPE(self)
 thread_module_state *state = get_thread_state(module)
 ...
}
```

See also [PEP 573](https://peps.python.org/pep-0573/) [https://peps.python.org/pep-0573/].

## Writing a custom converter

As we hinted at in the previous section... you can write your own converters! A converter is simply a Python class that inherits from `CConverter`. The main purpose of a custom converter is if you have a parameter using the `O&` format unit—parsing this parameter means calling a `PyArg_ParseTuple()` “converter function”.

Your converter class should be named `*something*_converter`. If the name follows this convention, then your converter class will be automatically registered with Argument Clinic; its name will be the name of your class with the `_converter` suffix stripped off. (This is accomplished with a metaclass.)

You shouldn't subclass `CConverter.__init__`. Instead, you should write a `converter_init()` function. `converter_init()` always accepts a `self` parameter; after that, all additional parameters *must* be keyword-only. Any arguments passed in to the converter in Argument Clinic will be passed along to your `converter_init()`.

There are some additional members of `CConverter` you may wish to specify in your subclass. Here's the current list:

`type`

The C type to use for this variable. `type` should be a Python string specifying the type, e.g. `int`. If this is a pointer type, the type string should end with `'*'`.

`default`

The Python default value for this parameter, as a Python value. Or the magic value `unspecified` if there is no default.

`py_default`

`default` as it should appear in Python code, as a string. Or `None` if there is no default.

`c_default`

`default` as it should appear in C code, as a string. Or `None` if there is no default.

`c_ignored_default`

The default value used to initialize the C variable when there is no default, but not specifying a default may result in an “uninitialized variable” warning. This can easily happen when using option groups—although properly written code will never actually use this value, the variable does get passed in to the impl, and the C compiler will complain about the “use” of the uninitialized value. This value should always be a non-empty string.

`converter`

The name of the C converter function, as a string.

`impl_by_reference`

A boolean value. If true, Argument Clinic will add a `&` in front of the name of the variable when passing it into the `impl` function.

`parse_by_reference`

A boolean value. If true, Argument Clinic will add a `&` in front of the name of the variable when passing it into `PyArg_ParseTuple()`.

Here's the simplest example of a custom converter, from `Modules/zlibmodule.c`:

```
/*[python input]
```

```
class ssize_t_converter(CConverter):
 type = 'Py_ssize_t'
 converter = 'ssize_t_converter'
```

```
[python start generated code]*/
```

```
/*[python end generated code: output=da39a3ee5e6b4b0d in
```

This block adds a converter to Argument Clinic named `ssize_t`. Parameters declared as `ssize_t` will be declared as type `Py_ssize_t`, and will be parsed by the `'O&'` format unit, which will call the `ssize_t_converter` converter function. `ssize_t` variables automatically support default values.

More sophisticated custom converters can insert custom C code to handle initialization and cleanup. You can see more examples of custom converters in the CPython source tree; grep the C files for the string `CConverter`.

## Writing a custom return converter

Writing a custom return converter is much like writing a custom converter. Except it's somewhat simpler, because return converters are themselves much simpler.

Return converters must subclass `CReturnConverter`. There are

no examples yet of custom return converters, because they are not widely used yet. If you wish to write your own return converter, please read `Tools/clinic/clinic.py`, specifically the implementation of `CReturnConverter` and all its subclasses.

## METH\_O and METH\_NOARGS

To convert a function using `METH_O`, make sure the function's single argument is using the `object` converter, and mark the arguments as positional-only:

```
/*[clinic input]
meth_o_sample

 argument: object
/
[clinic start generated code]*/
```

To convert a function using `METH_NOARGS`, just don't specify any arguments.

You can still use a self converter, a return converter, and specify a `type` argument to the `object` converter for `METH_O`.

## tp\_new and tp\_init functions

You can convert `tp_new` and `tp_init` functions. Just name them `__new__` or `__init__` as appropriate. Notes:

- The function name generated for `__new__` doesn't end in `__new__` like it would by default. It's just the name of the class, converted into a valid C identifier.
- No `PyMethodDef #define` is generated for these functions.
- `__init__` functions return `int`, not `PyObject *`.
- Use the docstring as the class docstring.
- Although `__new__` and `__init__` functions must always accept both the `args` and `kwargs` objects, when converting you may specify any signature for these functions that you like. (If your function doesn't support keywords, the parsing

function generated will throw an exception if it receives any.)

## Changing and redirecting Clinic's output

It can be inconvenient to have Clinic's output interspersed with your conventional hand-edited C code. Luckily, Clinic is configurable: you can buffer up its output for printing later (or earlier!), or write its output to a separate file. You can also add a prefix or suffix to every line of Clinic's generated output.

While changing Clinic's output in this manner can be a boon to readability, it may result in Clinic code using types before they are defined, or your code attempting to use Clinic-generated code before it is defined. These problems can be easily solved by rearranging the declarations in your file, or moving where Clinic's generated code goes. (This is why the default behavior of Clinic is to output everything into the current block; while many people consider this hampers readability, it will never require rearranging your code to fix definition-before-use problems.)

Let's start with defining some terminology:

### *field*

A field, in this context, is a subsection of Clinic's output. For example, the `#define` for the `PyMethodDef` structure is a field, called `methoddef_define`. Clinic has seven different fields it can output per function definition:

```
docstring_prototype
docstring_definition
methoddef_define
impl_prototype
parser_prototype
parser_definition
impl_definition
```

All the names are of the form "`<a>_<b>`", where "`<a>`" is the semantic object represented (the parsing function, the `impl` function, the `docstring`, or the `methoddef` structure) and "`<b>`" represents what kind of statement the field is. Field

names that end in `"_prototype"` represent forward declarations of that thing, without the actual body/data of the thing; field names that end in `"_definition"` represent the actual definition of the thing, with the body/data of the thing. (`"methoddef"` is special, it's the only one that ends with `"_define"`, representing that it's a preprocessor `#define`.)

### *destination*

A destination is a place Clinic can write output to. There are five built-in destinations:

#### `block`

The default destination: printed in the output section of the current Clinic block.

#### `buffer`

A text buffer where you can save text for later. Text sent here is appended to the end of any existing text. It's an error to have any text left in the buffer when Clinic finishes processing a file.

#### `file`

A separate "clinic file" that will be created automatically by Clinic. The filename chosen for the file is `{basename}.clinic{extension}`, where `basename` and `extension` were assigned the output from `os.path.splitext()` run on the current file. (Example: the `file` destination for `_pickle.c` would be written to `_pickle.clinic.c`.)

**Important: When using a `file` destination, you must check in the generated file!**

#### `two-pass`

A buffer like `buffer`. However, a two-pass buffer can only be dumped once, and it prints out all text sent to it during all processing, even from Clinic blocks *after* the dumping point.

suppress

The text is suppressed—thrown away.

Clinic defines five new directives that let you reconfigure its output.

The first new directive is `dump`:

```
dump <destination>
```

This dumps the current contents of the named destination into the output of the current block, and empties it. This only works with `buffer` and `two-pass` destinations.

The second new directive is `output`. The most basic form of `output` is like this:

```
output <field> <destination>
```

This tells Clinic to output *field* to *destination*. `output` also supports a special meta-destination, called `everything`, which tells Clinic to output *all* fields to that *destination*.

`output` has a number of other functions:

```
output push
output pop
output preset <preset>
```

`output push` and `output pop` allow you to push and pop configurations on an internal configuration stack, so that you can temporarily modify the output configuration, then easily restore the previous configuration. Simply push before your change to save the current configuration, then pop when you wish to restore the previous configuration.

`output preset` sets Clinic's output to one of several built-in preset configurations, as follows:

```
block
```

Clinic's original starting configuration. Writes everything immediately after the input block.

Suppress the `parser_prototype` and `docstring_prototype`, write everything else to `block`.

`file`

Designed to write everything to the “clinic file” that it can. You then `#include` this file near the top of your file. You may need to rearrange your file to make this work, though usually this just means creating forward declarations for various `typedef` and `PyObject` definitions.

Suppress the `parser_prototype` and `docstring_prototype`, write the `impl_definition` to `block`, and write everything else to `file`.

The default filename is `"{dirname}/clinic/{basename}.h"`.

`buffer`

Save up most of the output from Clinic, to be written into your file near the end. For Python files implementing modules or builtin types, it’s recommended that you dump the buffer just above the static structures for your module or builtin type; these are normally very near the end. Using `buffer` may require even more editing than `file`, if your file has static `PyMethodDef` arrays defined in the middle of the file.

Suppress the `parser_prototype`, `impl_prototype`, and `docstring_prototype`, write the `impl_definition` to `block`, and write everything else to `file`.

`two-pass`

Similar to the `buffer preset`, but writes forward declarations to the `two-pass buffer`, and definitions to the `buffer`. This is similar to the `buffer preset`, but may require less editing than `buffer`. Dump the `two-pass buffer` near the top of your file, and dump the `buffer` near the end just like you would when using the `buffer preset`.

Suppresses the `impl_prototype`, write the `impl_definition` to `block`, write `docstring_prototype`, `methoddef_define`, and `parser_prototype` to `two-pass`, write everything else to `buffer`.

#### `partial-buffer`

Similar to the `buffer preset`, but writes more things to `block`, only writing the really big chunks of generated code to `buffer`. This avoids the definition-before-use problem of `buffer` completely, at the small cost of having slightly more stuff in the `block`'s output. Dump the `buffer` near the end, just like you would when using the `buffer preset`.

Suppresses the `impl_prototype`, write the `docstring_definition` and `parser_definition` to `buffer`, write everything else to `block`.

The third new directive is `destination`:

```
destination <name> <command> [...]
```

This performs an operation on the destination named `name`.

There are two defined subcommands: `new` and `clear`.

The `new` subcommand works like this:

```
destination <name> new <type>
```

This creates a new destination with name <name> and type <type>.

There are five destination types:

`suppress`

Throws the text away.

`block`

Writes the text to the current block. This is what Clinic originally did.

`buffer`

A simple text buffer, like the “buffer” builtin destination above.

`file`

A text file. The file destination takes an extra argument, a template to use for building the filename, like so:

```
destination <name> new
<type> <file_template>
```

The template can use three strings internally that will be replaced by bits of the filename:

`{path}`

The full path to the file, including directory and full filename.

`{dirname}`

The name of the directory the file is in.

`{basename}`

Just the name of the

file, not including the directory.

`{basename_root}`

Basename with the extension clipped off (everything up to but not including the last '.').

`{basename_extension}`

The last '.' and everything after it. If the basename does not contain a period, this will be the empty string.

If there are no periods in the filename, `{basename}` and `{filename}` are the same, and `{extension}` is empty. "`{basename}{extension}`" is always exactly the same as "`{filename}`".

`two-pass`

A two-pass buffer, like the "two-pass" builtin destination above.

The `clear` subcommand works like this:

```
destination <name> clear
```

It removes all the accumulated text up to this point in the destination. (I don't know what you'd need this for, but I thought maybe it'd be useful while someone's experimenting.)

The fourth new directive is `set`:

```
set line_prefix "string"
set line_suffix "string"
```

`set` lets you set two internal variables in Clinic. `line_prefix` is a string that will be prepended to every line of Clinic's output; `line_suffix` is a string that will be appended to every line of Clinic's output.

Both of these support two format strings:

```
{block comment start}
 Turns into the string /*, the start-comment
 text sequence for C files.
```

```
{block comment end}
 Turns into the string */, the end-comment
 text sequence for C files.
```

The final new directive is one you shouldn't need to use directly, called `preserve`:

```
preserve
```

This tells Clinic that the current contents of the output should be kept, unmodified. This is used internally by Clinic when dumping output into `file` files; wrapping it in a Clinic block lets Clinic use its existing checksum functionality to ensure the file was not modified by hand before it gets overwritten.

## The `#ifdef` trick

If you're converting a function that isn't available on all platforms, there's a trick you can use to make life a little easier. The existing code probably looks like this:

```
#ifdef HAVE_FUNCTIONNAME
static module_functionname(...)
{
 ...
}
#endif /* HAVE_FUNCTIONNAME */
```

And then in the `PyMethodDef` structure at the bottom the existing code will have:

```
#ifdef HAVE_FUNCTIONNAME
{'functionname', ... },
#endif /* HAVE_FUNCTIONNAME */
```

In this scenario, you should enclose the body of your impl function inside the `#ifdef`, like so:

```
#ifdef HAVE_FUNCTIONNAME
/*[clinic input]
module.functionname
...
[clinic start generated code]*/
static module_functionname(...)
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```

Then, remove those three lines from the `PyMethodDef` structure, replacing them with the macro `Argument Clinic` generated:

```
MODULE_FUNCTIONNAME_METHODDEF
```

(You can find the real name for this macro inside the generated code. Or you can calculate it yourself: it's the name of your function as defined on the first line of your block, but with periods changed to underscores, uppercased, and `"_METHODDEF"` added to the end.)

Perhaps you're wondering: what if `HAVE_FUNCTIONNAME` isn't defined? The `MODULE_FUNCTIONNAME_METHODDEF` macro won't be defined either!

Here's where `Argument Clinic` gets very clever. It actually detects that the `Argument Clinic` block might be deactivated by the `#ifdef`. When that happens, it generates a little extra code that looks like this:

```
#ifndef MODULE_FUNCTIONNAME_METHODDEF
#define MODULE_FUNCTIONNAME_METHODDEF
#endif /* !defined(MODULE_FUNCTIONNAME_METHODDEF) */
```

That means the macro always works. If the function is defined, this turns into the correct structure, including the trailing comma. If the function is undefined, this turns into nothing.

However, this causes one ticklish problem: where should Argument Clinic put this extra code when using the “block” output preset? It can’t go in the output block, because that could be deactivated by the `#ifdef`. (That’s the whole point!)

In this situation, Argument Clinic writes the extra code to the “buffer” destination. This may mean that you get a complaint from Argument Clinic:

```
Warning in file "Modules/posixmodule.c" on line 12357:
Destination buffer 'buffer' not empty at end of file, em
```

When this happens, just open your file, find the `dump buffer` block that Argument Clinic added to your file (it’ll be at the very bottom), then move it above the `PyMethodDef` structure where that macro is used.

## Using Argument Clinic in Python files

It’s actually possible to use Argument Clinic to preprocess Python files. There’s no point to using Argument Clinic blocks, of course, as the output wouldn’t make any sense to the Python interpreter. But using Argument Clinic to run Python blocks lets you use Python as a Python preprocessor!

Since Python comments are different from C comments, Argument Clinic blocks embedded in Python files look slightly different. They look like this:

```
#!/*[python input]
#print("def foo(): pass")
#[python start generated code]*/
def foo(): pass
#!/*[python checksum:...]*/
```

# Instrumenting CPython with DTrace and SystemTap

author

David Malcolm

author

Łukasz Langa

DTrace and SystemTap are monitoring tools, each providing a way to inspect what the processes on a computer system are doing. They both use domain-specific languages allowing a user to write scripts which:

- filter which processes are to be observed
- gather data from the processes of interest
- generate reports on the data

As of Python 3.6, CPython can be built with embedded “markers”, also known as “probes”, that can be observed by a DTrace or SystemTap script, making it easier to monitor what the CPython processes on a system are doing.

**CPython implementation detail:** DTrace markers are implementation details of the CPython interpreter. No guarantees are made about probe compatibility between versions of CPython. DTrace scripts can stop working or work incorrectly without warning when changing CPython versions.

## Enabling the static markers

macOS comes with built-in support for DTrace. On Linux, in order to build CPython with the embedded markers for SystemTap, the SystemTap development tools must be installed.

On a Linux machine, this can be done via:

```
$ yum install systemtap-sdt-devel
```

or:

```
$ sudo apt-get install systemtap-sdt-dev
```

CPython must then be **configured with the `--with-dtrace` option**:

```
checking for --with-dtrace... yes
```

On macOS, you can list available DTrace probes by running a Python process in the background and listing all probes made available by the Python provider:

```
$ python3.6 -q &
$ sudo dtrace -l -P python$! # or: dtrace -l -m python3
```

ID	PROVIDER	MODULE	
29564	python18035	python3.6	_PyEval_Eval
29565	python18035	python3.6	dtrace_fu
29566	python18035	python3.6	_PyEval_Eval
29567	python18035	python3.6	dtrace_fun
29568	python18035	python3.6	
29569	python18035	python3.6	
29570	python18035	python3.6	_PyEval_Eval
29571	python18035	python3.6	maybe

On Linux, you can verify if the SystemTap static markers are present in the built binary by seeing if it contains a “.note.stapsdt” section.

```
$ readelf -S ./python | grep .note.stapsdt
[30] .note.stapsdt NOTE 0000000000000000
```

If you’ve built Python as a shared library (with the **`--enable-shared`** configure option), you need to look instead within the shared library. For example:

```
$ readelf -S libpython3.3dm.so.1.0 | grep .note.stapsdt
[29] .note.stapsdt NOTE 0000000000000000
```

Sufficiently modern readelf can print the metadata:

```
$ readelf -n ./python
```

Location: 0x000000000053dba8, Base: 0x0000000000

Arguments: 8@%rbp 8@%r12 -4@%eax

The above metadata contains information for SystemTap describing how it can patch strategically placed machine code instructions to

enable the tracing hooks used by a SystemTap script.

## Static DTrace probes

The following example DTrace script can be used to show the call/return hierarchy of a Python script, only tracing within the invocation of a function called “start”. In other words, import-time function invocations are not going to be listed:

```
self int indent;
```

```
python$target:::function-entry
/copyinstr(arg1) == "start"/
{
 self->trace = 1;
}
```

```
python$target:::function-entry
/self->trace/
{
 printf("%d\t%s:", timestamp, 15, probename);
 printf("%s", self->indent, "");
 printf("%s:%s:%d\n", basename(copyinstr(arg0)),
 self->indent++);
}
```

```
python$target:::function-return
/self->trace/
{
 self->indent--;
 printf("%d\t%s:", timestamp, 15, probename);
 printf("%s", self->indent, "");
 printf("%s:%s:%d\n", basename(copyinstr(arg0)),
 self->indent--);
}
```

```
python$target:::function-return
/copyinstr(arg1) == "start"/
{
```

```
 self->trace = 0;
 }
```

It can be invoked like this:

```
$ sudo dtrace -q -s call_stack.d -c "python3.6 script.py"
```

The output looks like this:

```
156641360502280 function-entry:call_stack.py:start:23
156641360518804 function-entry: call_stack.py:function_
156641360532797 function-entry: call_stack.py:function
156641360546807 function-return: call_stack.py:function
156641360563367 function-return: call_stack.py:function_
156641360578365 function-entry: call_stack.py:function_
156641360591757 function-entry: call_stack.py:function
156641360605556 function-entry: call_stack.py:functio
156641360617482 function-return: call_stack.py:functio
156641360629814 function-return: call_stack.py:function
156641360642285 function-return: call_stack.py:function_
156641360656770 function-entry: call_stack.py:function_
156641360669707 function-return: call_stack.py:function_
156641360687853 function-entry: call_stack.py:function_
156641360700719 function-return: call_stack.py:function_
156641360719640 function-entry: call_stack.py:function_
156641360732567 function-return: call_stack.py:function_
156641360747370 function-return:call_stack.py:start:28
```

## Static SystemTap markers

The low-level way to use the SystemTap integration is to use the static markers directly. This requires you to explicitly state the binary file containing them.

For example, this SystemTap script can be used to show the call/return hierarchy of a Python script:

```
probe process("python").mark("function__entry") {
 filename = user_string($arg1);
```

```

 funcname = user_string($arg2);
 lineno = $arg3;

 printf("%s => %s in %s:%d\\n",
 thread_indent(1), funcname, filename, lineno);
}

probe process("python").mark("function__return") {
 filename = user_string($arg1);
 funcname = user_string($arg2);
 lineno = $arg3;

 printf("%s <= %s in %s:%d\\n",
 thread_indent(-1), funcname, filename, lineno);
}

```

It can be invoked like this:

```

$ stap \
 show-call-hierarchy.stp \
 -c "./python test.py"

```

The output looks like this:

```

11408 python(8274): => __contains__ in Lib/_abcoll
11414 python(8274): => __getitem__ in Lib/os.py:
11418 python(8274): => encode in Lib/os.py:490
11424 python(8274): <= encode in Lib/os.py:493
11428 python(8274): <= __getitem__ in Lib/os.py:
11433 python(8274): <= __contains__ in Lib/_abcoll

```

where the columns are:

- time in microseconds since start of script
- name of executable
- PID of process

and the remainder indicates the call/return hierarchy as the script executes.

For a `--enable-shared` build of CPython, the markers are contained within the libpython shared library, and the probe's dotted path needs to reflect this. For example, this line from the above example:

```
probe process("python").mark("function__entry") {
```

should instead read:

```
probe process("python").library("libpython3.6dm.so.1.0")
```

(assuming a `debug build` of CPython 3.6)

## Available static markers

`function_entry(str filename, str funcname, int lineno)`

This marker indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

The filename, function name, and line number are provided back to the tracing script as positional arguments, which must be accessed using `$arg1`, `$arg2`, `$arg3`:

- `$arg1`: (const char \*) filename, accessible using `user_string($arg1)`
- `$arg2`: (const char \*) function name, accessible using `user_string($arg2)`
- `$arg3`: int line number

`function_return(str filename, str funcname, int lineno)`

This marker is the converse of `function_entry()`, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-Python (bytecode) functions.

The arguments are the same as for `function_entry()`

`line(str filename, str funcname, int lineno)`

This marker indicates a Python line is about to be executed. It is the equivalent of line-by-line tracing with a Python profiler. It is not triggered within C functions.

The arguments are the same as for `function__entry()`.

`gc_start(int generation)`

Fires when the Python interpreter starts a garbage collection cycle. `arg0` is the generation to scan, like `gc.collect()`.

`gc_done(long collected)`

Fires when the Python interpreter finishes a garbage collection cycle. `arg0` is the number of collected objects.

`import_find_load_start(str modulename)`

Fires before `importlib` attempts to find and load the module. `arg0` is the module name.

*New in version 3.7.*

`import_find_load_done(str modulename, int found)`

Fires after `importlib`'s `find_and_load` function is called. `arg0` is the module name, `arg1` indicates if module was successfully loaded.

*New in version 3.7.*

`audit(str event, void *tuple)`

Fires when `sys.audit()` or `PySys_Audit()` is called. `arg0` is the event name as C string, `arg1` is a `PyObject` pointer to a tuple object.

*New in version 3.8.*

## SystemTap Tapsets

The higher-level way to use the SystemTap integration is to use a

“tapset”: SystemTap’s equivalent of a library, which hides some of the lower-level details of the static markers.

Here is a tapset file, based on a non-shared build of CPython:

```
/*
 Provide a higher-level wrapping around the function__
 function__return markers:
 */
probe python.function.entry = process("python").mark("fu
{
 filename = user_string($arg1);
 funcname = user_string($arg2);
 lineno = $arg3;
 frameptr = $arg4
}
probe python.function.return = process("python").mark("f
{
 filename = user_string($arg1);
 funcname = user_string($arg2);
 lineno = $arg3;
 frameptr = $arg4
}
```

If this file is installed in SystemTap’s tapset directory (e.g. `/usr/share/systemtap/tapset`), then these additional probepoints become available:

`python.function.entry(str filename, str funcname, int lineno, frameptr)`

This probe point indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

`python.function.return(str filename, str funcname, int lineno, frameptr)`

This probe point is the converse of `python.function.entry`, and indicates that execution of a Python function has ended (either via `return`, or via an

exception). It is only triggered for pure-Python (bytecode) functions.

## Examples

This SystemTap script uses the tapset above to more cleanly implement the example given above of tracing the Python function-call hierarchy, without needing to directly name the static markers:

```
probe python.function.entry
{
 printf("%s => %s in %s:%d\n",
 thread_indent(1), funcname, filename, lineno);
}

probe python.function.return
{
 printf("%s <= %s in %s:%d\n",
 thread_indent(-1), funcname, filename, lineno);
}
```

The following script uses the tapset above to provide a top-like view of all running CPython code, showing the top 20 most frequently entered bytecode frames, each second, across the whole system:

```
global fn_calls;

probe python.function.entry
{
 fn_calls[pid(), filename, funcname, lineno] += 1;
}

probe timer.ms(1000) {
 printf("\033[2J\033[1;1H") /* clear screen */
 printf("%6s %80s %6s %30s %6s\n",
 "PID", "FILENAME", "LINE", "FUNCTION", "CALLS");
 foreach ([pid, filename, funcname, lineno] in fn_calls)
 printf("%6d %80s %6d %30s %6d\n",
 pid, filename, lineno, funcname,
```

```
 fn_calls[pid, filename, funcname, lineno]);
 }
 delete fn_calls;
}
```

# Annotations Best Practices

author

Larry Hastings

## Abstract

This document is designed to encapsulate the best practices for working with annotations dicts. If you write Python code that examines `__annotations__` on Python objects, we encourage you to follow the guidelines described below.

The document is organized into four sections: best practices for accessing the annotations of an object in Python versions 3.10 and newer, best practices for accessing the annotations of an object in Python versions 3.9 and older, other best practices for `__annotations__` that apply to any Python version, and quirks of `__annotations__`.

Note that this document is specifically about working with `__annotations__`, not uses *for* annotations. If you're looking for information on how to use "type hints" in your code, please see the [typing](#) module.

## Accessing The Annotations Dict Of An Object In Python 3.10 And Newer

Python 3.10 adds a new function to the standard library: `inspect.get_annotations()`. In Python versions 3.10 and newer, calling this function is the best practice for accessing the annotations dict of any object that supports annotations. This function can also "un-stringize" stringized annotations for you.

If for some reason

`inspect.get_annotations()` isn't viable for your use case, you may access the `__annotations__` data member manually. Best practice for this changed in Python 3.10 as well: as of Python 3.10, `o.__annotations__` is guaranteed to *always* work on Python functions, classes, and modules. If you're certain the object you're examining is one of these three *specific* objects, you may simply use `o.__annotations__` to get at the object's annotations dict.

However, other types of callables—for example, callables created by `functools.partial()`—may not have an `__annotations__` attribute defined. When accessing the `__annotations__` of a possibly unknown object, best practice in Python versions 3.10 and newer is to call `getattr()` with three arguments, for example `getattr(o, '__annotations__', None)`.

Before Python 3.10, accessing `__annotations__` on a class that defines no annotations but that has a parent class with annotations would return the parent's `__annotations__`. In Python 3.10 and newer, the child class's annotations will be an empty dict instead.

## Accessing The Annotations Dict Of An Object In Python 3.9 And Older

In Python 3.9 and older, accessing the annotations dict of an object is much more complicated than in newer versions. The problem is a design flaw in these older versions of Python, specifically to do with class annotations.

Best practice for accessing the annotations dict of

other objects—functions, other callables, and modules—is the same as best practice for 3.10, assuming you aren’t calling `inspect.get_annotations()`: you should use three-argument `getattr()` to access the object’s `__annotations__` attribute.

Unfortunately, this isn’t best practice for classes. The problem is that, since `__annotations__` is optional on classes, and because classes can inherit attributes from their base classes, accessing the `__annotations__` attribute of a class may inadvertently return the annotations dict of a *base class*. As an example:

```
class Base:
 a: int = 3
 b: str = 'abc'

class Derived(Base):
 pass

print(Derived.__annotations__)
```

This will print the annotations dict from `Base`, not `Derived`.

Your code will have to have a separate code path if the object you’re examining is a class (`isinstance(o, type)`). In that case, best practice relies on an implementation detail of Python 3.9 and before: if a class has annotations defined, they are stored in the class’s `__dict__` dictionary. Since the class may or may not have annotations defined, best practice is to call the `get` method on the class dict.

To put it all together, here is some sample code that safely accesses the `__annotations__` attribute on an arbitrary object in Python 3.9 and

before:

```
if isinstance(o, type):
 ann = o.__dict__.get('__annotations__', None)
else:
 ann = getattr(o, '__annotations__', None)
```

After running this code, `ann` should be either a dictionary or `None`. You're encouraged to double-check the type of `ann` using `isinstance()` before further examination.

Note that some exotic or malformed type objects may not have a `__dict__` attribute, so for extra safety you may also wish to use `getattr()` to access `__dict__`.

## Manually Un-Stringizing Stringized Annotations

In situations where some annotations may be “stringized”, and you wish to evaluate those strings to produce the Python values they represent, it really is best to call `inspect.get_annotations()` to do this work for you.

If you're using Python 3.9 or older, or if for some reason you can't use `inspect.get_annotations()`, you'll need to duplicate its logic. You're encouraged to examine the implementation of `inspect.get_annotations()` in the current Python version and follow a similar approach.

In a nutshell, if you wish to evaluate a stringized annotation on an arbitrary object `o`:

- If `o` is a module, use `o.__dict__` as the `globals` when calling `eval()`.

- If `o` is a class, use `sys.modules[o.__module__].__dict__` as the globals, and `dict(vars(o))` as the locals, when calling `eval()`.
- If `o` is a wrapped callable using `functools.update_wrapper()`, `functools.wraps()`, or `functools.partial()`, iteratively unwrap it by accessing either `o.__wrapped__` or `o.func` as appropriate, until you have found the root unwrapped function.
- If `o` is a callable (but not a class), use `o.__globals__` as the globals when calling `eval()`.

However, not all string values used as annotations can be successfully turned into Python values by `eval()`. String values could theoretically contain any valid string, and in practice there are valid use cases for type hints that require annotating with string values that specifically *can't* be evaluated. For example:

- **PEP 604** [<https://peps.python.org/pep-0604/>] union types using `|`, before support for this was added to Python 3.10.
- Definitions that aren't needed at runtime, only imported when `typing.TYPE_CHECKING` is true.

If `eval()` attempts to evaluate such values, it will fail and raise an exception. So, when designing a library API that works with annotations, it's recommended to only attempt to evaluate string values when explicitly requested to by the caller.

## Best Practices For `__annotations__` In Any Python Version

- You should avoid assigning to the `__annotations__` member of objects directly. Let Python manage setting `__annotations__`.
- If you do assign directly to the `__annotations__` member of an object, you should always set it to a `dict` object.
- If you directly access the `__annotations__` member of an object, you should ensure that it's a dictionary before attempting to examine its contents.
- You should avoid modifying `__annotations__` dicts.
- You should avoid deleting the `__annotations__` attribute of an object.

## `__annotations__` Quirks

In all versions of Python 3, function objects lazy-create an annotations dict if no annotations are defined on that object. You can delete the `__annotations__` attribute using `del fn.__annotations__`, but if you then access `fn.__annotations__` the object will create a new empty dict that it will store and return as its annotations. Deleting the annotations on a function before it has lazily created its annotations dict will throw an `AttributeError`; using `del fn.__annotations__` twice in a row is guaranteed to always throw an `AttributeError`.

Everything in the above paragraph also applies to class and module objects in Python 3.10 and newer.

In all versions of Python 3, you can set `__annotations__` on a function object to `None`. However, subsequently accessing the annotations on that object using `fn.__annotations__` will lazy-create an empty dictionary as per the first paragraph of this section. This is *not* true of

modules and classes, in any Python version; those objects permit setting `__annotations__` to any Python value, and will retain whatever value is set.

If Python stringizes your annotations for you (using `from __future__ import annotations`), and you specify a string as an annotation, the string will itself be quoted. In effect the annotation is quoted *twice*. For example:

```
from __future__ import annotations
def foo(a: "str"): pass

print(foo.__annotations__)
```

This prints `{'a': "'str'"}`. This shouldn't really be considered a “quirk”; it's mentioned here simply because it might be surprising.

# Isolating Extension Modules

## Abstract

Traditionally, state belonging to Python extension modules was kept in C `static` variables, which have process-wide scope. This document describes problems of such per-process state and shows a safer way: per-module state.

The document also describes how to switch to per-module state where possible. This transition involves allocating space for that state, potentially switching from static types to heap types, and—perhaps most importantly—accessing per-module state from code.

## Who should read this

This guide is written for maintainers of [C-API](#) extensions who would like to make that extension safer to use in applications where Python itself is used as a library.

## Background

An *interpreter* is the context in which Python code runs. It contains configuration (e.g. the import path) and runtime state (e.g. the set of imported modules).

Python supports running multiple interpreters in one process. There are two cases to think about—users may run interpreters:

- in sequence, with several `Py_InitializeEx()` / `Py_FinalizeEx()` cycles, and
- in parallel, managing “sub-interpreters” using `Py_NewInterpreter()` / `Py_EndInterpreter()`.

Both cases (and combinations of them) would be most useful when embedding Python within a library. Libraries generally shouldn't make assumptions about the application that uses them, which include assuming a process-wide “main Python interpreter”.

Historically, Python extension modules don't handle this use case well. Many extension modules (and even some stdlib modules) use *per-process* global state, because C `static` variables are extremely easy to use. Thus, data that should be specific to an interpreter ends up being shared between interpreters. Unless the extension developer is careful, it is very easy to introduce edge cases that lead to crashes when a module is loaded in more than one interpreter in the same process.

Unfortunately, *per-interpreter* state is not easy to achieve. Extension authors tend to not keep multiple interpreters in mind when developing, and it is currently cumbersome to test the behavior.

## Enter Per-Module State

Instead of focusing on per-interpreter state, Python's C API is evolving to better support the more granular *per-module* state. This means that C-level data is be attached to a *module object*. Each interpreter creates its own module object, keeping the data separate. For testing the isolation, multiple module objects corresponding to a single extension can even be loaded in a single interpreter.

Per-module state provides an easy way to think about lifetime and resource ownership: the extension module will initialize when a module object is created, and clean up when it's freed. In this regard, a module is just like any other [PyObject\\*](#); there are no “on interpreter shutdown” hooks to think—or forget—about.

Note that there are use cases for different kinds of “globals”: per-process, per-interpreter, per-thread or per-task state. With per-module state as the default, these are still possible, but you should treat them as exceptional cases: if you need them, you should give them additional care and testing. (Note that this guide does not cover them.)

## Isolated Module Objects

The key point to keep in mind when developing an extension module is that several module objects can be created from a single shared library. For example:

```
>>> import sys
>>> import binascii
>>> old_binascii = binascii
>>> del sys.modules['binascii']
>>> import binascii # create a new module object
>>> old_binascii == binascii
False
```

As a rule of thumb, the two modules should be completely independent. All objects and state specific to the module should be encapsulated within the module object, not shared with other module objects, and cleaned up when the module object is deallocated. Since this just is a rule of thumb, exceptions are possible (see [Managing Global State](#)), but they will need more thought and attention to edge cases.

While some modules could do with less stringent restrictions, isolated modules make it easier to set clear expectations and guidelines that work across a variety of use cases.

## Surprising Edge Cases

Note that isolated modules do create some surprising edge cases. Most notably, each module object will typically not share its classes and exceptions with other similar modules. Continuing from the [example above](#), note that `old_binascii.Error` and `binascii.Error` are separate objects. In the following code, the exception is *not* caught:

```
>>> old_binascii.Error == binascii.Error
False
>>> try:
... old_binascii.unhexlify(b'qwertyuiop')
... except binascii.Error:
```

```
... print('boo')
...
Traceback (most recent call last):
 File "<stdin>", line 2, in <module>
binascii.Error: Non-hexadecimal digit found
```

This is expected. Notice that pure-Python modules behave the same way: it is a part of how Python works.

The goal is to make extension modules safe at the C level, not to make hacks behave intuitively. Mutating `sys.modules` “manually” counts as a hack.

## Making Modules Safe with Multiple Interpreters

### Managing Global State

Sometimes, the state associated with a Python module is not specific to that module, but to the entire process (or something else “more global” than a module). For example:

- The `readline` module manages *the* terminal.
- A module running on a circuit board wants to control *the* on-board LED.

In these cases, the Python module should provide *access* to the global state, rather than *own* it. If possible, write the module so that multiple copies of it can access the state independently (along with other libraries, whether for Python or other languages). If that is not possible, consider explicit locking.

If it is necessary to use process-global state, the simplest way to avoid issues with multiple interpreters is to explicitly prevent a module from being loaded more than once per process—see [Opt-Out: Limiting to One Module Object per Process](#).

### Managing Per-Module State

To use per-module state, use [multi-phase extension module initialization](#). This signals that your module supports multiple interpreters correctly.

Set `PyModuleDef.m_size` to a positive number to request that many bytes of storage local to the module. Usually, this will be set to the size of some module-specific `struct`, which can store all of the module's C-level state. In particular, it is where you should put pointers to classes (including exceptions, but excluding static types) and settings (e.g. `csv`'s [field\\_size\\_limit](#)) which the C code needs to function.

### Note

Another option is to store state in the module's `__dict__`, but you must avoid crashing when users modify `__dict__` from Python code. This usually means error- and type-checking at the C level, which is easy to get wrong and hard to test sufficiently.

However, if module state is not needed in C code, storing it in `__dict__` only is a good idea.

If the module state includes `PyObject` pointers, the module object must hold references to those objects and implement the module-level hooks `m_traverse`, `m_clear` and `m_free`. These work like `tp_traverse`, `tp_clear` and `tp_free` of a class. Adding them will require some work and make the code longer; this is the price for modules which can be unloaded cleanly.

An example of a module with per-module state is currently available as [xxlimited](#) [<https://github.com/python/cpython/blob/master/Modules/xxlimited.c>]; example module initialization shown at the bottom of the file.

## Opt-Out: Limiting to One Module Object per Process

A non-negative `PyModuleDef.m_size` signals that a module supports multiple interpreters correctly. If this is not yet the case for your module, you can explicitly make your module loadable only once per process. For example:

```
static int loaded = 0;

static int
exec_module(PyObject* module)
{
 if (loaded) {
 PyErr_SetString(PyExc_ImportError,
 "cannot load module more than once")
 return -1;
 }
 loaded = 1;
 // ... rest of initialization
}
```

## Module State Access from Functions

Accessing the state from module-level functions is straightforward. Functions get the module object as their first argument; for extracting the state, you can use `PyModule_GetState`:

```
static PyObject *
func(PyObject *module, PyObject *args)
{
 my_struct *state = (my_struct*)PyModule_GetState(module);
 if (state == NULL) {
 return NULL;
 }
 // ... rest of logic
}
```

### Note

`PyModule_GetState` may return `NULL` without setting an exception if there is no module state, i.e.

`PyModuleDef.m_size` was zero. In your own module, you're in control of `m_size`, so this is easy to prevent.

## Heap Types

Traditionally, types defined in C code are *static*; that is, `static PyObject` structures defined directly in code and initialized using `PyType_Ready()`.

Such types are necessarily shared across the process. Sharing them between module objects requires paying attention to any state they own or access. To limit the possible issues, static types are immutable at the Python level: for example, you can't set `str.myattribute = 123`.

**CPython implementation detail:** Sharing truly immutable objects between interpreters is fine, as long as they don't provide access to mutable objects. However, in CPython, every Python object has a mutable implementation detail: the reference count. Changes to the `refcount` are guarded by the GIL. Thus, code that shares any Python objects across interpreters implicitly depends on CPython's current, process-wide GIL.

Because they are immutable and process-global, static types cannot access “their” module state. If any method of such a type requires access to module state, the type must be converted to a *heap-allocated type*, or *heap type* for short. These correspond more closely to classes created by Python's `class` statement.

For new modules, using heap types by default is a good rule of thumb.

## Changing Static Types to Heap Types

Static types can be converted to heap types, but note that the heap type API was not designed for “lossless” conversion from static types—that is, creating a type that works exactly like a given static type. So, when rewriting the class definition in a new API, you are likely to unintentionally change a few details (e.g. pickleability or inherited slots). Always test the details that are important to you.

Watch out for the following two points in particular (but note that this is not a comprehensive list):

- Unlike static types, heap type objects are mutable by default. Use the `Py_TPFLAGS_IMMUTABLETYPE` flag to prevent

mutability.

- Heap types inherit `tp_new` by default, so it may become possible to instantiate them from Python code. You can prevent this with the `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag.

## Defining Heap Types

Heap types can be created by filling a `PyType_Spec` structure, a description or “blueprint” of a class, and calling `PyType_FromModuleAndSpec()` to construct a new class object.

### Note

Other functions, like `PyType_FromSpec()`, can also create heap types, but `PyType_FromModuleAndSpec()` associates the module with the class, allowing access to the module state from methods.

The class should generally be stored in *both* the module state (for safe access from C) and the module’s `__dict__` (for access from Python code).

## Garbage-Collection Protocol

Instances of heap types hold a reference to their type. This ensures that the type isn’t destroyed before all its instances are, but may result in reference cycles that need to be broken by the garbage collector.

To avoid memory leaks, instances of heap types must implement the garbage collection protocol. That is, heap types should:

- Have the `Py_TPFLAGS_HAVE_GC` flag.
- Define a traverse function using `Py_tp_traverse`, which visits the type (e.g. using `Py_VISIT(Py_TYPE(self))`).

Please refer to the [the documentation](#) of `Py_TPFLAGS_HAVE_GC` and `tp_traverse` for additional considerations.

If your traverse function delegates to the `tp_traverse` of its base class (or another type), ensure that `Py_TYPE(self)` is visited only once. Note that only heap type are expected to visit the type in `tp_traverse`.

For example, if your traverse function includes:

```
base->tp_traverse(self, visit, arg)
```

...and `base` may be a static type, then it should also include:

```
if (base->tp_flags & Py_TPFLAGS_HEAPTYPE) {
 // a heap type's tp_traverse already visited Py_TYPE
} else {
 Py_VISIT(Py_TYPE(self));
}
```

It is not necessary to handle the type's reference count in `tp_new` and `tp_clear`.

## Module State Access from Classes

If you have a type object defined with

`PyType_FromModuleAndSpec()`, you can call `PyType_GetModule()` to get the associated module, and then `PyModule_GetState()` to get the module's state.

To save a some tedious error-handling boilerplate code, you can combine these two steps with `PyType_GetModuleState()`, resulting in:

```
my_struct *state = (my_struct*)PyType_GetModuleState(type)
if (state == NULL) {
 return NULL;
}
```

## Module State Access from Regular Methods

Accessing the module-level state from methods of a class is somewhat more complicated, but is possible thanks to API

introduced in Python 3.9. To get the state, you need to first get the *defining class*, and then get the module state from it.

The largest roadblock is getting *the class a method was defined in*, or that method's “defining class” for short. The defining class can have a reference to the module it is part of.

Do not confuse the defining class with `Py_TYPE(self)`. If the method is called on a *subclass* of your type, `Py_TYPE(self)` will refer to that subclass, which may be defined in different module than yours.

## Note

The following Python code can illustrate the concept.

`Base.get_defining_class` returns `Base` even if `type(self) == Sub`:

```
class Base:
 def get_type_of_self(self):
 return type(self)

 def get_defining_class(self):
 return __class__

class Sub(Base):
 pass
```

For a method to get its “defining class”, it must use the **`METH_METHOD` | `METH_FASTCALL` | `METH_KEYWORDS`** [calling convention](#) and the corresponding `PyCMethod` signature:

```
PyObject *PyCMethod(
 PyObject *self, // object the method was called on
 PyTypeObject *defining_class, // defining class
 PyObject *const *args, // C array of argument pointers
 Py_ssize_t nargs, // length of "args"
 PyObject *kwnames) // NULL, or dict of keyword names
```

Once you have the defining class, call

`PyType_GetModuleState()` to get the state of its associated module.

For example:

```
static PyObject *
example_method(PyObject *self,
 PyTypeObject *defining_class,
 PyObject *const *args,
 Py_ssize_t nargs,
 PyObject *kwnames)
{
 my_struct *state = (my_struct*)PyType_GetModuleState(
 if (state == NULL) {
 return NULL;
 }
 ... // rest of logic
 }
```

```
PyDoc_STRVAR(example_method_doc, "...");
```

```
static PyMethodDef my_methods[] = {
 {"example_method",
 (PyCFunction) (void (*)(void)) example_method,
 METH_METHOD | METH_FASTCALL | METH_KEYWORDS,
 example_method_doc},
 {NULL},
}
```

## Module State Access from Slot Methods, Getters and Setters

### Note

This is new in Python 3.11.

Slot methods—the fast C equivalents for special methods, such as `nb_add` for `__add__` or `tp_new` for initialization—have a very

simple API that doesn't allow passing in the defining class, unlike with `PyCMethod`. The same goes for getters and setters defined with `PyGetSetDef`.

To access the module state in these cases, use the `PyType_GetModuleByDef()` function, and pass in the module definition. Once you have the module, call `PyModule_GetState()` to get the state:

```
PyObject *module = PyType_GetModuleByDef(Py_TYPE(self),
my_struct *state = (my_struct*)PyModule_GetState(module)
if (state == NULL) {
 return NULL;
}
```

`PyType_GetModuleByDef` works by searching the [method resolution order](#) (i.e. all superclasses) for the first superclass that has a corresponding module.

## Note

In very exotic cases (inheritance chains spanning multiple modules created from the same definition), `PyType_GetModuleByDef` might not return the module of the true defining class. However, it will always return a module with the same definition, ensuring a compatible C memory layout.

## Lifetime of the Module State

When a module object is garbage-collected, its module state is freed. For each pointer to (a part of) the module state, you must hold a reference to the module object.

Usually this is not an issue, because types created with `PyType_FromModuleAndSpec()`, and their instances, hold a reference to the module. However, you must be careful in reference counting when you reference module state from other places, such as callbacks for external libraries.

# Open Issues

Several issues around per-module state and heap types are still open.

Discussions about improving the situation are best held on the [capi-sig mailing list](https://mail.python.org/mailman3/lists/capi-sig.python.org/) [https://mail.python.org/mailman3/lists/capi-sig.python.org/].

## Per-Class Scope

It is currently (as of Python 3.11) not possible to attach state to individual *types* without relying on CPython implementation details (which may change in the future—perhaps, ironically, to allow a proper solution for per-class scope).

## Lossless Conversion to Heap Types

The heap type API was not designed for “lossless” conversion from static types; that is, creating a type that works exactly like a given static type.

## General Information

### What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. It supports multiple programming paradigms beyond object-oriented programming, such as procedural and functional programming. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C + + . It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants including Linux and macOS, and on Windows.

To find out more, start with [The Python Tutorial](#). The [Beginner's Guide to Python](#) [<https://wiki.python.org/moin/BeginnersGuide>] links to other introductory tutorials and resources for learning Python.

### What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF's mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF's home page is at <https://www.python.org/psf/>.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via [the PSF donation page](#)

[<https://www.python.org/psf/donations/>].

## Are there copyright restrictions on the use of Python?

You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See [the PSF license page](https://www.python.org/psf/license/) [<https://www.python.org/psf/license/>] to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult [the Trademark Usage Policy](https://www.python.org/psf/trademarks/) [<https://www.python.org/psf/trademarks/>] for more information.

## Why was Python created in the first place?

Here's a *very* brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of

Modula-3 and read the Modula-3 report. Modula-3 is the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the `Misc/HISTORY` file.

## What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating differences between files), internet protocols (HTTP, FTP, SMTP,

XML-RPC, POP, IMAP), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for [The Python Standard Library](#) to get an idea of what's available. A wide variety of third-party extensions are also available. Consult [the Python Package Index](https://pypi.org) [https://pypi.org] to find packages of interest to you.

## How does the Python version numbering scheme work?

Python versions are numbered “A.B.C” or “A.B”:

- A is the major version number – it is only incremented for really major changes in the language.
- B is the minor version number – it is incremented for less earth-shattering changes.
- C is the micro version number – it is incremented for each bugfix release.

See [PEP 6](https://peps.python.org/pep-0006/) [https://peps.python.org/pep-0006/] for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren't yet finalized; it's not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix:

- The suffix for an alpha version is “aN” for some small number N.
- The suffix for a beta version is “bN” for some small number N.
- The suffix for a release candidate version is “rcN” for some

small number  $N$ .

In other words, all versions labeled  $2.0aN$  precede the versions labeled  $2.0bN$ , which precede versions labeled  $2.0cN$ , and *those* precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the CPython development repository. In practice, after a final minor release is made, the version is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

## How do I obtain a copy of the Python source?

The latest Python source distribution is always available from python.org, at <https://www.python.org/downloads/>. The latest development sources can be obtained at <https://github.com/python/cpython/>.

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the [Getting Started section of the Python Developer’s Guide](#) [<https://devguide.python.org/setup/>] for more information on getting the source code and compiling it.

## How do I get documentation on Python?

The standard documentation for the current stable version of Python is available at <https://docs.python.org/3/>. PDF, plain text, and downloadable HTML versions are also available at <https://docs.python.org/3/download.html>.

The documentation is written in reStructuredText and processed by [the Sphinx documentation tool](#) [<https://www.sphinx-doc.org/>]. The

reStructuredText source for the documentation is part of the Python source distribution.

## I've never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes [The Python Tutorial](#).

Consult [the Beginner's Guide](#) [<https://wiki.python.org/moin/BeginnersGuide>] to find information for beginning Python programmers, including lists of tutorials.

## Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, [python-list](#) [<https://mail.python.org/mailman/listinfo/python-list>]. The newsgroup and mailing list are gatewayed into each other – if you can read news it's unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in *comp.lang.python.announce*, a low-traffic moderated list that receives about five postings per day. It's available as [the python-announce mailing list](#) [<https://mail.python.org/mailman/listinfo/python-announce-list>].

More info about other mailing lists and newsgroups can be found at <https://www.python.org/community/lists/>.

## How do I get a beta test version of Python?

Alpha and beta releases are available from <https://www.python.org/downloads/>. All releases are announced on the *comp.lang.python* and *comp.lang.python.announce* newsgroups and on the Python home page at <https://www.python.org/>; an RSS feed of news is available.

You can also access the development version of Python through Git. See [The Python Developer's Guide](https://devguide.python.org/) [https://devguide.python.org/] for details.

## How do I submit bug reports and patches for Python?

To report a bug or submit a patch, use the issue tracker at <https://github.com/python/cpython/issues>.

For more information on how Python is developed, consult [the Python Developer's Guide](https://devguide.python.org/) [https://devguide.python.org/].

## Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.

The [very first article](https://ir.cwi.nl/pub/18204) [https://ir.cwi.nl/pub/18204] about Python was written in 1991 and is now quite outdated.

Guido van Rossum and Jelke de Boer, “Interactively Testing Remote Servers Using the Python Programming Language”, CWI Quarterly, Volume 4, Issue 4 (December 1991), Amsterdam, pp 283–303.

## Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at <https://wiki.python.org/moin/PythonBooks> for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

## Where in the world is [www.python.org](https://www.python.org) located?

The Python project's infrastructure is located all over the world and is managed by the Python Infrastructure Team. Details [here](https://www.python.org/infrastructure/) [https://

infra.psf.io].

## Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “[Monty Python’s Flying Circus](https://en.wikipedia.org/wiki/Monty_Python)” [https://en.wikipedia.org/wiki/Monty\_Python], a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

## Do I have to like “Monty Python’s Flying Circus”?

No, but it helps. :)

## Python in the real world

### How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. As of version 3.9, Python will have a major new release every 12 months ([PEP 602](https://peps.python.org/pep-0602/) [https://peps.python.org/pep-0602/]).

The developers issue “bugfix” releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 3.5.3, 3.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it’s guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the [Python download page](https://www.python.org/downloads/) [https://www.python.org/downloads/]. There are two production-ready versions of Python: 2.x and 3.x. The recommended version is 3.x, which is supported by most widely used libraries. Although 2.x is still widely used, [it is not maintained anymore](https://peps.python.org/pep-0373/) [https://peps.python.org/pep-0373/].

### How many people are using Python?

There are probably millions of users, though it's difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it's available from many different sites and packaged with many Linux distributions, so download statistics don't tell the whole story either.

The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

## Have any significant projects been done in Python?

See <https://www.python.org/about/success> for a list of projects that use Python. Consulting the proceedings for [past Python conferences](https://www.python.org/community/workshops/) [https://www.python.org/community/workshops/] will reveal contributions from many different companies and organizations.

High-profile Python projects include [the Mailman mailing list manager](https://www.list.org) [https://www.list.org] and [the Zope application server](https://www.zope.dev) [https://www.zope.dev]. Several Linux distributions, most notably [Red Hat](https://www.redhat.com) [https://www.redhat.com], have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

## What new developments are expected for Python in the future?

See <https://peps.python.org/> for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled "Python X.Y Release Schedule", where X.Y is a version that hasn't been publicly released yet.

New development is discussed on [the python-dev mailing list](https://mail.python.org/mailman/listinfo/python-dev/) [https://mail.python.org/mailman/listinfo/python-dev/].

## Is it reasonable to propose incompatible changes to Python?

In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there's still the problem of updating all documentation; many books have been written about Python, and we don't want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** [<https://peps.python.org/pep-0005/>] describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

## Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be

assigned programming projects very early in the course that *do* something. Assignments aren't restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```
>>> L = []
>>> dir(L)
['__add__', '__class__', '__contains__', '__delattr__',
 '__dir__', '__doc__', '__eq__', '__format__', '__ge__',
 '__getattr__', '__getitem__', '__gt__', '__hash__',
 '__imul__', '__init__', '__iter__', '__le__', '__len__',
 '__mul__', '__ne__', '__new__', '__reduce__', '__reduce_',
 '__repr__', '__reversed__', '__rmul__', '__setattr__',
 '__sizeof__', '__str__', '__subclasshook__', 'append',
 'copy', 'count', 'extend', 'index', 'insert', 'pop', 're',
 'reverse', 'sort']
>>> [d for d in dir(L) if '__' not in d]
['append', 'clear', 'copy', 'count', 'extend', 'index',
'append(...)'
 L.append(object) -> None -- append object to end

>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as they are programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult [the Python wiki](https://wiki.python.org/moin/PythonEditors) [https://wiki.python.org/moin/PythonEditors] for a full list of Python editing environments.

If you want to discuss Python's use in education, you may be interested in joining [the edu-sig mailing list](https://www.python.org/community/sigs/current/edu-sig) [https://www.python.org/community/sigs/current/edu-sig].

## Python?

- How do I copy an object in Python?
- How can I find the methods or attributes of an object?
- How can my code discover the name of an object?
- What's up with the comma operator's precedence?
- Is there an equivalent of C's "?:" ternary operator?
- Is it possible to write obfuscated one-liners in Python?
- What does the slash(/) in the parameter list of a function mean?

## ○ Numbers and strings

- How do I specify hexadecimal and octal integers?
- Why does `-22 // 10` return `-3`?
- How do I get int literal attribute instead of `SyntaxError`?
- How do I convert a string to a number?
- How do I convert a number to a string?
- How do I modify a string in place?
- How do I use strings to call functions/methods?
- Is there an equivalent to Perl's `chomp()` for removing trailing newlines from strings?
- Is there a `scanf()` or `sscanf()` equivalent?
- What does 'UnicodeDecodeError' or 'UnicodeEncodeError' error mean?
- Can I end a raw string with an odd number of backslashes?

## ○ Performance

- My program is too slow. How do I speed it up?
- What is the most efficient way to concatenate many strings together?

## ○ Sequences (Tuples/Lists)

- How do I convert between tuples and lists?
- What's a negative index?

- How do I iterate over a sequence in reverse order?
- How do you remove duplicates from a list?
- How do you remove multiple items from a list?
- How do you make an array in Python?
- How do I create a multidimensional list?
- How do I apply a method or function to a sequence of objects?
- Why does `a_tuple[i] += ['item']` raise an exception when the addition works?
- I want to do a complicated sort: can you do a Schwartzian Transform in Python?
- How can I sort one list by values from another list?

## ○ Objects

- What is a class?
- What is a method?
- What is `self`?
- How do I check if an object is an instance of a given class or of a subclass of it?
- What is delegation?
- How do I call a method defined in a base class from a derived class that extends it?
- How can I organize my code to make it easier to change the base class?
- How do I create static class data and static class methods?
- How can I overload constructors (or methods) in Python?
- I try to use `__spam` and I get an error about `__SomeClassName_spam`.
- My class defines `__del__` but it is not called when I delete the object.
- How do I get a list of all instances of a given class?
- Why does the result of `id()` appear to be not unique?
- When can I rely on identity tests with the `is` operator?
- How can a subclass control what data is

- stored in an immutable instance?
- How do I cache method calls?
- Modules
  - How do I create a .pyc file?
  - How do I find the current module name?
  - How can I have modules that mutually import each other?
  - `_import__('x.y.z')` returns <module 'x'>; how do I get z?
  - When I edit an imported module and reimport it, the changes don't show up. Why does this happen?

## General Questions

### Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

Several debuggers for Python are described below, and the built-in function `breakpoint()` allows you to drop into any of them.

The `pdb` module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is [documented in the Library Reference Manual](#). You can also write your own debugger by using the code for `pdb` as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as [Tools/scripts/idle3](#) [<https://github.com/python/cpython/blob/main/Tools/scripts/idle3>]), includes a graphical debugger.

PythonWin is a Python IDE that includes a GUI debugger based on `pdb`. The PythonWin debugger colors breakpoints and has quite a few cool features such as debugging non-PythonWin programs. PythonWin is available as part of [pywin32](#) [<https://github.com/mhammond/pywin32>] project and as a part of the [ActivePython](#) [<https://www.activestate.com/products/python/>] distribution.

**Eric** [<https://eric-ide.python-projects.org/>] is an IDE built on PyQt and the Scintilla editing component.

**trepan3k** [<https://github.com/rocky/python3-trepan/>] is a gdb-like debugger.

**Visual Studio Code** [<https://code.visualstudio.com/>] is an IDE with debugging tools that integrates with version-control software.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- **Wing IDE** [<https://wingware.com/>]
- **Komodo IDE** [<https://www.activestate.com/products/komodo-ide/>]
- **PyCharm** [<https://www.jetbrains.com/pycharm/>]

## Are there tools to help find bugs or perform static analysis?

Yes.

**Pylint** [<https://pylint.pycqa.org/en/latest/index.html>] and **Pyflakes** [<https://github.com/PyCQA/pyflakes>] do basic checking that will help you catch bugs sooner.

Static type checkers such as **Mypy** [<http://mypy-lang.org/>], **Pyre** [<https://pyre-check.org/>], and **Pytype** [<https://github.com/google/pytype>] can check type hints in Python source code.

## How can I create a stand-alone binary from a Python script?

You don't need the ability to compile Python to C code if all you want is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as **Tools/freeze** [<https://github.com/python/cpython/tree/main/Tools/>]

freeze]. It converts Python byte code to C arrays; with a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

The following packages can help with the creation of console and GUI executables:

- [Nuitka](https://nuitka.net/) [https://nuitka.net/] (Cross-platform)
- [PyInstaller](https://pyinstaller.org/) [https://pyinstaller.org/] (Cross-platform)
- [PyOxidizer](https://pyoxidizer.readthedocs.io/en/stable/) [https://pyoxidizer.readthedocs.io/en/stable/] (Cross-platform)
- [cx\\_Freeze](https://marcelotduarte.github.io/cx_Freeze/) [https://marcelotduarte.github.io/cx\_Freeze/] (Cross-platform)
- [py2app](https://github.com/ronaldoussoren/py2app) [https://github.com/ronaldoussoren/py2app] (macOS only)
- [py2exe](https://www.py2exe.org/) [https://www.py2exe.org/] (Windows only)

## Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as [PEP 8](https://peps.python.org/pep-0008/) [https://peps.python.org/pep-0008/].

## Core Language

### Why am I getting an `UnboundLocalError` when the variable has a value?

It can be a surprise to get the `UnboundLocalError` in previously

working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```
>>> x = 10
>>> def bar():
... print(x)
...
>>> bar()
10
```

works, but this code:

```
>>> x = 10
>>> def foo():
... print(x)
... x += 1
```

results in an **UnboundLocalError**:

```
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any similarly named variable in the outer scope. Since the last statement in `foo` assigns a new value to `x`, the compiler recognizes it as a local variable. Consequently when the earlier `print(x)` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```
>>> x = 10
>>> def foobar():
... global x
... print(x)
... x += 1
```

```
...
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```
>>> print(x)
11
```

You can do a similar thing in a nested scope using the **nonlocal** keyword:

```
>>> def foo():
... x = 10
... def bar():
... nonlocal x
... print(x)
... x += 1
... bar()
... print(x)
...
>>> foo()
10
11
```

## What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a value anywhere within the function's body, it's assumed to be a local unless explicitly declared as global.

Though a bit surprising at first, a moment's consideration explains this. On one hand, requiring **global** for assigned variables provides a bar against unintended side-effects. On the other hand, if **global** was required for all global references, you'd be using

`global` all the time. You'd have to declare as `global` every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

## Why do lambdas defined in a loop with different values all return the same result?

Assume you use a `for` loop to define a few different lambdas (or even plain functions), e.g.:

```
>>> squares = []
>>> for x in range(5):
... squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate `x**2`. You might expect that, when called, they would return, respectively, 0, 1, 4, 9, and 16. However, when you actually try you will see that they all return 16:

```
>>> squares[2]()
16
>>> squares[4]()
16
```

This happens because `x` is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of `x` is 4, so all the functions now return `4**2`, i.e. 16. You can also verify this by changing the value of `x` and see how the results of the lambdas change:

```
>>> x = 8
>>> squares[2]()
64
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don't rely on the value of the global `x`:

```
>>> squares = []
```

```
>>> for x in range(5):
... squares.append(lambda n=x: n**2)
```

Here, `n=x` creates a new variable `n` local to the lambda and computed when the lambda is defined so that it has the same value that `x` had at that point in the loop. This means that the value of `n` will be 0 in the first lambda, 1 in the second, 2 in the third, and so on. Therefore each lambda will now return the correct result:

```
>>> squares[2]()
4
>>> squares[4]()
16
```

Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

## How do I share global variables across modules?

The canonical way to share information across modules within a single program is to create a special module (often called `config` or `cfg`). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

`config.py`:

```
x = 0 # Default value of the 'x' configuration setting
```

`mod.py`:

```
import config
config.x = 1
```

`main.py`:

```
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the singleton design pattern, for the same reason.

## What are the “best practices” for using import in a module?

In general, don't use `from module_name import *`. Doing so clutters the importer's namespace, and makes it much harder for linters to detect undefined names.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It's good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `argparse`, `re`
2. third-party library modules (anything installed in Python's site-packages directory) – e.g. `dateutil`, `requests`, `PIL`, `Image`
3. locally developed modules

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “`import <module>`” form of import. They fail when the 2nd module wants to grab a name out of the first (“`from module import name`”) and the import is at the top level. That's because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of

code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

## Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```
def foo(mydict={}): # Danger: shared reference to one dict
 ... compute something ...
 mydict[key] = value
 return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such

as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don't write:

```
def foo(mydict={}):
 ...
```

but:

```
def foo(mydict=None):
 if mydict is None:
 mydict = {} # create a new dict for local names
```

This feature can be useful. When you have a function that's time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called “memoizing”, and can be implemented like this:

```
Callers can only provide two parameters and optionally
def expensive(arg1, arg2, *, _cache={}):
 if (arg1, arg2) in _cache:
 return _cache[(arg1, arg2)]

 # Calculate the value
 result = ... expensive computation ...
 _cache[(arg1, arg2)] = result # Store result
 return result
```

You could use a global variable containing a dictionary instead of the default value; it's a matter of taste.

## How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the `*` and `**` specifiers in the

function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using `*` and `**`:

```
def f(x, *args, **kwargs):
 ...
 kwargs['width'] = '14.3c'
 ...
 g(x, *args, **kwargs)
```

## What is the difference between arguments and parameters?

**Parameters** are defined by the names that appear in a function definition, whereas **arguments** are the values actually passed to a function when calling it. Parameters define what **kind of arguments** a function can accept. For example, given the function definition:

```
def func(foo, bar=None, **kwargs):
 pass
```

*foo*, *bar* and *kwargs* are parameters of `func`. However, when calling `func`, for example:

```
func(42, bar=314, extra=somevar)
```

the values `42`, `314`, and `somevar` are arguments.

## Why did changing list 'y' also change list 'x'?

If you wrote code like:

```
>>> x = []
>>> y = x
>>> y.append(10)
>>> y
[10]
>>> x
[10]
```

you might be wondering why appending an element to `y` changed `x` too.

There are two factors that produce this result:

1. Variables are simply names that refer to objects. Doing `y = x` doesn't create a copy of the list – it creates a new variable `y` that refers to the same object `x` refers to. This means that there is only one object (the list), and both `x` and `y` refer to it.
2. Lists are [mutable](#), which means that you can change their content.

After the call to `append()`, the content of the mutable object has changed from `[]` to `[10]`. Since both the variables refer to the same object, using either name accesses the modified value `[10]`.

If we instead assign an immutable object to `x`:

```
>>> x = 5 # ints are immutable
>>> y = x
>>> x = x + 1 # 5 can't be mutated, we are creating a new object
>>> x
6
>>> y
5
```

we can see that in this case `x` and `y` are not equal anymore. This is because integers are [immutable](#), and when we do `x = x + 1` we are not mutating the int `5` by incrementing its value; instead, we are creating a new object (the int `6`) and assigning it to `x` (that is, changing which object `x` refers to). After this assignment we have two objects (the ints `6` and `5`) and two variables that refer to them (`x` now refers to `6` but `y` still refers to `5`).

Some operations (for example `y.append(10)` and `y.sort()`) mutate the object, whereas superficially similar operations (for example `y = y + [10]` and `sorted(y)`) create a new object. In general in Python (and in all cases in the standard library) a method that mutates an object will return `None` to help avoid getting the two types of operations confused. So if you mistakenly

write `y.sort()` thinking it will give you a sorted copy of `y`, you'll instead end up with `None`, which will likely cause your program to generate an easily diagnosed error.

However, there is one class of operations where the same operation sometimes has different behaviors with different types: the augmented assignment operators. For example, `+=` mutates lists but not tuples or ints (`a_list += [1, 2, 3]` is equivalent to `a_list.extend([1, 2, 3])` and mutates `a_list`, whereas `some_tuple += (1, 2, 3)` and `some_int += 1` create new objects).

In other words:

- If we have a mutable object (**list**, **dict**, **set**, etc.), we can use some specific operations to mutate it and all the variables that refer to it will see the change.
- If we have an immutable object (**str**, **int**, **tuple**, etc.), all the variables that refer to it will always see the same value, but operations that transform that value into a new value always return a new object.

If you want to know if two variables refer to the same object or not, you can use the **is** operator, or the built-in function **id()**.

## How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

### 1. By returning a tuple of the results:

```
>>> def func1(a, b):
... a = 'new-value' # a and b are local
... b = b + 1 # assigned to new ob
... return a, b # return new values
```

```
...
>>> x, y = 'old-value', 99
>>> func1(x, y)
('new-value', 100)
```

This is almost always the clearest solution.

2. By using global variables. This isn't thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```
>>> def func2(a):
... a[0] = 'new-value' # 'a' references a mutable object
... a[1] = a[1] + 1 # changes a shared object in-place
...
>>> args = ['old-value', 99]
>>> func2(args)
>>> args
['new-value', 100]
```

4. By passing in a dictionary that gets mutated:

```
>>> def func3(args):
... args['a'] = 'new-value' # args is a mutable object
... args['b'] = args['b'] + 1 # change it in-place
...
>>> args = {'a': 'old-value', 'b': 99}
>>> func3(args)
>>> args
{'a': 'new-value', 'b': 100}
```

5. Or bundle up values in a class instance:

```
>>> class Namespace:
... def __init__(self, /, **args):
... for key, value in args.items():
... setattr(self, key, value)
...
>>> def func4(args):
```

```

... args.a = 'new-value' # args is a mut
... args.b = args.b + 1 # change object
...
>>> args = Namespace(a='old-value', b=99)
>>> func4(args)
>>> vars(args)
{'a': 'new-value', 'b': 100}

```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.

## How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a,b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```

def linear(a, b):
 def result(x):
 return a * x + b
 return result

```

Or using a callable object:

```

class linear:
 def __init__(self, a, b):
 self.a, self.b = a, b

 def __call__(self, x):
 return self.a * x + self.b

```

In both cases,

```
taxes = linear(0.3, 2)
```

gives a callable object where `taxes(10e6) == 0.3 * 10e6 + 2`.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

```
class exponential(linear):
 # __init__ inherited
 def __call__(self, x):
 return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

```
class counter:

 value = 0

 def set(self, x):
 self.value = x

 def up(self):
 self.value = self.value + 1

 def down(self):
 self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

## How do I copy an object in Python?

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:

```
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```
new_l = l[:]
```

## How can I find the methods or attributes of an object?

For an instance `x` of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

## How can my code discover the name of an object?

Generally speaking, it can't, because objects don't really have names. Essentially, assignment always binds a name to a value; the same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```
>>> class A:
... pass
...
>>> B = A
>>> a = B()
>>> b = a
>>> print(b)
<__main__.A object at 0x16D07CC>
>>> print(a)
<__main__.A object at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name `B` the created instance is still reported as an instance of class `A`. However, it is impossible to say whether the instance's name is `a` or `b`, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In `comp.lang.python`, Fredrik Lundh once gave an excellent analogy

in answer to this question:

The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn't really care – so the only way to find out what it's called is to ask all your neighbours (namespaces) if it's their cat (object)...

....and don't be surprised if you'll find that it's known by many names, or no name at all!

## What's up with the comma operator's precedence?

Comma is not an operator in Python. Consider this session:

```
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```
("a" in "b"), "a"
```

not:

```
"a" in ("b", "a")
```

The same is true of the various assignment operators (=, += etc). They are not truly operators but syntactic delimiters in assignment statements.

## Is there an equivalent of C's “?:” ternary operator?

Yes, there is. The syntax is as follows:

```
[on_true] if [expression] else [on_false]
```

```
x, y = 50, 25
small = x if x < y else y
```

Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when *on\_true* has a false boolean value. Therefore, it is always better to use the ... if ... else ... form.

## Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting `lambda` within `lambda`. See the following three examples, slightly adapted from Ulf Bartelt:

```
from functools import reduce
```

```
Primes < 1000
```

```
print(list(filter(None,map(lambda y:y*reduce(lambda x,y:
map(lambda x,y=y:y%x,range(2,int(pow(y,0.5)+1))),1),rang
```

```
First 10 Fibonacci numbers
```

```
print(list(map(lambda x,f=lambda x,f:(f(x-1,f)+f(x-2,f))
f(x,f), range(10))))
```

```
Mandelbrot set
```

```
print((lambda Ru,Ro,Iu,Io,IM,Sx,Sy:reduce(lambda x,y:x+
Iu=Iu,Io=Io,Ru=Ru,Ro=Ro,Sy=Sy,L=lambda yc,Iu=Iu,Io=Io,Ru
Sx=Sx,Sy=Sy:reduce(lambda x,y:x+y,map(lambda x,xc=Ru,yc=
i=i,Sx=Sx,F=lambda xc,yc,x,y,k,f=lambda xc,yc,x,y,k,f:(k
>=4.0) or 1+f(xc,yc,x*x-y*y+xc,2.0*x*y+yc,k-1,f):f(xc,yc
64+F(Ru+x*(Ro-Ru)/Sx,yc,0,0,i)),range(Sx)):L(Iu+y*(Io-I
)))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24))
```

```
___ ___/ ___ ___/ | | |___ lines on screen
V V | |___ columns on screen
| | |___ maximum of "itera
| |___ range on y axis
|___ range on x axis
```

Don't try this at home, kids!

## What does the slash(/) in the parameter list of a function mean?

A slash in the argument list of a function denotes that the parameters prior to it are positional-only. Positional-only parameters are the ones without an externally usable name. Upon calling a function that accepts positional-only parameters, arguments are mapped to parameters based solely on their position. For example, `divmod()` is a function that accepts positional-only parameters. Its documentation looks like this:

```
>>> help(divmod)
Help on built-in function divmod in module builtins:

divmod(x, y, /)
 Return the tuple (x//y, x%y). Invariant: div*y + mo
```

The slash at the end of the parameter list means that both parameters are positional-only. Thus, calling `divmod()` with keyword arguments would lead to an error:

```
>>> divmod(x=3, y=4)
Traceback (most recent call last):
 File "<stdin>", line 1, in <module>
TypeError: divmod() takes no keyword arguments
```

## Numbers and strings

### How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

## Why does `-22 // 10` return `-3`?

It’s primarily driven by the desire that `i % j` have the same sign as `j`. If you want that, and also want:

```
i == (i // j) * j + (i % j)
```

then integer division has to return the floor. C also requires that identity to hold, and then compilers that truncate `i // j` need to make `i % j` have the same sign as `i`.

There are few real use cases for `i % j` when `j` is negative. When `j` is positive, there are many, and in virtually all of them it’s more useful for `i % j` to be  $\geq 0$ . If the clock says 10 now, what did it say 200 hours ago? `-190 % 12 == 2` is useful; `-190 % 12 == -10` is a bug waiting to bite.

## How do I get `int` literal attribute instead of `SyntaxError`?

Trying to lookup an `int` literal attribute in the normal manner gives a `SyntaxError` because the period is seen as a decimal point:

```
>>> 1.__class__
File "<stdin>", line 1
1.__class__
 ^
```

SyntaxError: invalid decimal literal

The solution is to separate the literal from the period with either a space or parentheses.

```
>>> 1.__class__
<class 'int'>
>>> (1).__class__
<class 'int'>
```

## How do I convert a string to a number?

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` holds true, and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python's rules: a leading '0o' indicates octal, and '0x' indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because Python does not allow leading '0' in a decimal number (except '0').

## How do I convert a number to a string?

To convert, e.g., the number 144 to the string '144', use the built-in type constructor `str()`. If you want a hexadecimal or octal representation, use the built-in functions `hex()` or `oct()`. For

fancy formatting, see the [Formatted string literals](#) and [Format String Syntax](#) sections, e.g. `"{:04d}".format(144)` yields `'0144'` and `"{: .3f}".format(1.0/3.0)` yields `'0.333'`.

## How do I modify a string in place?

You can't, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using an [io.StringIO](#) object or the [array](#) module:

```
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!")
6
>>> sio.getvalue()
'Hello, there!'

>>> import array
>>> a = array.array('u', s)
>>> print(a)
array('u', 'Hello, world')
>>> a[0] = 'y'
>>> print(a)
array('u', 'yello, world')
>>> a.tounicode()
'yello, world'
```

## How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions.

The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```
def a():
 pass
```

```
def b():
 pass
```

```
dispatch = {'go': a, 'stop': b} # Note lack of par

dispatch[get_input()]() # Note trailing parens to
```

- Use the built-in function `getattr()`:

```
import foo
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.

This is used in several places in the standard library, like this:

```
class Foo:
 def do_foo(self):
 ...

 def do_bar(self):
 ...

f = getattr(foo_instance, 'do_' + opname)
f()
```

- Use `locals()` to resolve the function name:

```
def myFunc():
 print("hello")

fname = "myFunc"
```

```
f = locals()[fname]
f()
```

## Is there an equivalent to Perl's `chomp()` for removing trailing newlines from strings?

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other trailing whitespace. If the string `S` represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```
>>> lines = ("line 1 \r\n"
... "\r\n"
... "\r\n")
>>> lines.rstrip("\n\r")
'line 1 '
```

Since this is typically only desired when reading text one line at a time, using `S.rstrip()` this way works well.

## Is there a `scanf()` or `sscanf()` equivalent?

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the `split()` method of string objects and then convert decimal strings to numeric values using `int()` or `float()`. `split()` supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C's `sscanf` and better suited for the task.

## What does ‘UnicodeDecodeError’ or ‘UnicodeEncodeError’ error mean?

See the [Unicode HOWTO](#).

## Can I end a raw string with an odd number of backslashes?

A raw string ending with an odd number of backslashes will escape the string's quote:

```
>>> r'C:\this\will\not\work\
File "<stdin>", line 1
 r'C:\this\will\not\work\
 ^
```

SyntaxError: unterminated string literal (detected at li

There are several workarounds for this. One is to use regular strings and double the backslashes:

```
>>> 'C:\\this\\will\\work\\'
'C:\\this\\will\\work\\'
```

Another is to concatenate a regular string containing an escaped backslash to the raw string:

```
>>> r'C:\this\will\work' '\\'
'C:\\this\\will\\work\\'
```

It is also possible to use `os.path.join()` to append a backslash on Windows:

```
>>> os.path.join(r'C:\this\will\work', '')
'C:\\this\\will\\work\\'
```

Note that while a backslash will “escape” a quote for the purposes of determining where the raw string ends, no escaping occurs when interpreting the value of the raw string. That is, the backslash remains present in the value of the raw string:

```
>>> r'backslash\'preserved'
"backslash\\'preserved"
```

Also see the specification in the [language reference](#).

# Performance

## My program is too slow. How do I speed it up?

That's a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focuses on [CPython](#).
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program *before* attempting to optimize any code (see the [profile](#) module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the [timeit](#) module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the [Built-in Types](#) and the [collections](#) module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the [list.sort\(\)](#) built-in method or the related [sorted\(\)](#) function to do sorting (and see the [Sorting HOW TO](#) for examples of moderately advanced usage).
- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be

slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, [Cython](https://cython.org) [https://cython.org] can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also [write a C extension module](#) yourself.

## See also

The wiki page devoted to [performance tips](https://wiki.python.org/moin/PythonSpeed/PerformanceTips) [https://wiki.python.org/moin/PythonSpeed/PerformanceTips].

## What is the most efficient way to concatenate many strings together?

**str** and **bytes** objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many **str** objects, the recommended idiom is to place them into a list and call **str.join()** at the end:

```
chunks = []
for s in my_strings:
 chunks.append(s)
result = ''.join(chunks)
```

(another reasonably efficient idiom is to use [io.StringIO](#))

To accumulate many **bytes** objects, the recommended idiom is to extend a **bytearray** object using in-place concatenation (the **+=** operator):

```
result = bytearray()
for b in my_bytes_objects:
 result += b
```

## Sequences (Tuples/Lists)

### How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields `('a', 'b', 'c')`. If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

### What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `S[:-1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.

### How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function:

```
for x in reversed(sequence):
 ... # do something with x ...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

## How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

<https://code.activestate.com/recipes/52560/>

If you don't mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```
if mylist:
 mylist.sort()
 last = mylist[-1]
 for i in range(len(mylist)-2, -1, -1):
 if last == mylist[i]:
 del mylist[i]
 else:
 last = mylist[i]
```

If all elements of the list may be used as set keys (i.e. they are all [hashable](#)) this is often faster

```
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

## How do you remove multiple items from a list

As with removing duplicates, explicitly iterating in reverse with a delete condition is one possibility. However, it is easier and faster to use slice replacement with an implicit or explicit forward iteration. Here are three variations.:

```
mylist[:] = filter(keep_function, mylist)
```

```
mylist[:] = (x for x in mylist if keep_condition)
mylist[:] = [x for x in mylist if keep_condition]
```

The list comprehension may be fastest.

## How do you make an array in Python?

Use a list:

```
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that [NumPy](https://numpy.org/) [https://numpy.org/] and other third party packages define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate *cons cells* using tuples:

```
lisp_list = ("like", ("this", ("example", None)))
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of a Lisp *car* is `lisp_list[0]` and the analogue of *cdr* is `lisp_list[1]`. Only do this if you're sure you really need to, because it's usually a lot slower than using Python lists.

## How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```
>>> A = [[None] * 2] * 3
```

This looks correct if you print it:

```
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn't create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```
A = [None] * 3
for i in range(3):
 A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```
w, h = 2, 3
A = [[None] * w for i in range(h)]
```

Or, you can use an extension that provides a matrix datatype; [NumPy](https://numpy.org/) [https://numpy.org/] is the best known.

## How do I apply a method or function to a sequence of objects?

To call a method or function and accumulate the return values in a list, a [list comprehension](#) is an elegant solution:

```
result = [obj.method() for obj in mylist]

result = [function(obj) for obj in mylist]
```

To just run the method or function without saving the return values, a plain **for** loop will suffice:

```
for obj in mylist:
 obj.method()
```

```
for obj in mylist:
 function(obj)
```

## Why does `a_tuple[i] += ['item']` raise an exception when the addition works?

This is because of a combination of the fact that augmented assignment operators are *assignment* operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we'll use a `list` and `+=` as our exemplar.

If you wrote:

```
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
```

```
...
```

```
TypeError: 'tuple' object does not support item assignment
```

The reason for the exception should be immediately clear: `1` is added to the object `a_tuple[0]` points to (`1`), producing the result object, `2`, but when we attempt to assign the result of the computation, `2`, to element `0` of the tuple, we get an error because we can't change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
Traceback (most recent call last):
```

```
...
```

```
TypeError: 'tuple' object does not support item assignment
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```
>>> a_tuple = (['foo'], 'bar')
>>> a_tuple[0] += ['item']
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```
>>> a_tuple[0]
['foo', 'item']
```

To see why this happens, you need to know that (a) if an object implements an `__iadd__()` magic method, it gets called when the `+=` augmented assignment is executed, and its return value is what gets used in the assignment statement; and (b) for lists, `__iadd__()` is equivalent to calling `extend()` on the list and returning the list. That's why we say that for lists, `+=` is a “shorthand” for `list.extend()`:

```
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```
>>> result = a_list.__iadd__([1])
>>> a_list = result
```

The object pointed to by `a_list` has been mutated, and the pointer to the mutated object is assigned back to `a_list`. The end result of the assignment is a no-op, since it is a pointer to the same object that `a_list` was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```
>>> result = a_tuple[0].__iadd__(['item'])
>>> a_tuple[0] = result
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```

The `__iadd__()` succeeds, and thus the list is extended, but even though `result` points to the same object that `a_tuple[0]` already points to, that final assignment still results in an error, because tuples are immutable.

## I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, use the `key` argument for the `list.sort()` method:

```
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

## How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```
>>> list1 = ["what", "I'm", "sorting", "by"]
>>> list2 = ["something", "else", "to", "sort"]
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[('I'm', 'else'), ('by', 'sort'), ('sorting', 'to'), ('what', 'something')]
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```

# Objects

## What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic `Mailbox` class that provides basic accessor methods for a mailbox, and subclasses such as `MboxMailbox`, `MaildirMailbox`, `OutlookMailbox` that handle various specific mailbox formats.

## What is a method?

A method is a function on some object `x` that you normally call as `x.name(arguments...)`. Methods are defined as functions inside the class definition:

```
class C:
 def meth(self, arg):
 return arg * 2 + self.attribute
```

## What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as `x.meth(a, b, c)` for some instance `x` of the class in which the definition occurs; the called method will think it is called as `meth(x, a, b, c)`.

See also [Why must 'self' be used explicitly in method definitions and calls?](#).

## How do I check if an object is an instance of a given

## class or of a subclass of it?

Use the built-in function `isinstance(obj, cls)`. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python's built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that `isinstance()` also checks for virtual inheritance from an [abstract base class](#). So, the test will return `True` for a registered class even if hasn't directly or indirectly inherited from it. To test for "true inheritance", scan the [MRO](#) of the class:

```
from collections.abc import Mapping

class P:
 pass

class C(P):
 pass

Mapping.register(P)

>>> c = C()
>>> isinstance(c, C) # direct
True
>>> isinstance(c, P) # indirect
True
>>> isinstance(c, Mapping) # virtual
True

Actual inheritance chain
>>> type(c).__mro__
(<class 'C'>, <class 'P'>, <class 'object'>)

Test for "true inheritance"
>>> Mapping in type(c).__mro__
False
```

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object's class and doing a different thing based on what class it is. For example, if you have a function that does something:

```
def search(obj):
 if isinstance(obj, Mailbox):
 ... # code to search a mailbox
 elif isinstance(obj, Document):
 ... # code to search a document
 elif ...
```

A better approach is to define a `search()` method on all the classes and just call it:

```
class Mailbox:
 def search(self):
 ... # code to search a mailbox

class Document:
 def search(self):
 ... # code to search a document

obj.search()
```

## What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you're interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```
class UpperOut:

 def __init__(self, outfile):
 self._outfile = outfile

 def write(self, s):
 self._outfile.write(s.upper())

 def __getattr__(self, name):
 return getattr(self._outfile, name)
```

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self._outfile.write()` method. All other methods are delegated to the underlying `self._outfile` object. The delegation is accomplished via the `__getattr__()` method; consult [the language reference](#) for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```
class X:
 ...
 def __setattr__(self, name, value):
 self.__dict__[name] = value
 ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for self without causing an infinite recursion.

## How do I call a method defined in a base class from a derived class that extends it?

Use the built-in `super()` function:

```
class Derived(Base):
 def meth(self):
 super().meth() # calls Base.meth
```

In the example, `super()` will automatically determine the instance from which it was called (the `self` value), look up the [method resolution order](#) (MRO) with `type(self).__mro__`, and return the next in line after `Derived` in the MRO: `Base`.

## How can I organize my code to make it easier to change the base class?

You could assign the base class to an alias and derive from the alias. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```
class Base:
 ...

BaseAlias = Base

class Derived(BaseAlias):
 ...
```

## How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value to the attribute, you have to explicitly use the class name in the assignment:

```
class C:
 count = 0 # number of times C.__init__ called
```

```
def __init__(self):
 C.count = C.count + 1

def getcount(self):
 return C.count # or return self.count
```

`c.count` also refers to `C.count` for any `c` such that `isinstance(c, C)` holds, unless overridden by `c` itself or by some class on the base-class search path from `c.__class__` back to `C`.

Caution: within a method of `C`, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in `self`’s own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```
C.count = 314
```

Static methods are possible:

```
class C:
 @staticmethod
 def static(arg1, arg2, arg3):
 # No 'self' parameter!
 ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:

```
def getcount():
 return C.count
```

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

## How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you'd write

```
class C {
 C() { cout << "No arguments\n"; }
 C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```
class C:
 def __init__(self, i=None):
 if i is None:
 print("No arguments")
 else:
 print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.

```
def __init__(self, *args):
 ...
```

The same approach works for all method definitions.

## **I try to use `_spam` and I get an error about `_SomeClassName_spam`.**

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `__classname_spam`, where `classname` is the current class name with any leading underscores stripped.

This doesn't guarantee privacy: an outside user can still deliberately access the `__classname_spam` attribute, and private values are visible in the object's `__dict__`. Many Python programmers never bother to use private variable names at all.

## My class defines `__del__` but it is not called when I delete the object.

There are several possible reasons for this.

The `del` statement does not necessarily call `__del__()` – it simply decrements the object’s reference count, and if this reaches zero `__del__()` is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your `__del__()` method may be called at an inconvenient and random time. This is inconvenient if you’re trying to reproduce a problem. Worse, the order in which object’s `__del__()` methods are executed is arbitrary. You can run `gc.collect()` to force a collection, but there *are* pathological cases where objects will never be collected.

Despite the cycle collector, it’s still a good idea to define an explicit `close()` method on objects to be called whenever you’re done with them. The `close()` method can then remove attributes that refer to subobjects. Don’t call `__del__()` directly – `__del__()` should call `close()` and `close()` should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the `weakref` module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your `__del__()` method raises an exception, a warning message is printed to `sys.stderr`.

## How do I get a list of all instances of a given class?

Python does not keep track of all instances of a class (or of a built-

in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.

## Why does the result of `id()` appear to be not unique?

The `id()` builtin returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object's memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

```
>>> id(1000)
13901272
>>> id(2000)
13901272
```

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the `id()` call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

```
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
```

## When can I rely on identity tests with the `is` operator?

The `is` operator tests for object identity. The test `a is b` is equivalent to `id(a) == id(b)`.

The most important property of an identity test is that an object is always identical to itself, `a is a` always returns `True`. Identity tests are usually faster than equality tests. And unlike equality tests, identity tests are guaranteed to return a boolean `True` or `False`.

However, identity tests can *only* be substituted for equality tests when object identity is assured. Generally, there are three

circumstances where identity is guaranteed:

1) Assignments create new names but do not change object identity. After the assignment `new = old`, it is guaranteed that `new` is `old`.

2) Putting an object in a container that stores object references does not change object identity. After the list assignment `s[0] = x`, it is guaranteed that `s[0]` is `x`.

3) If an object is a singleton, it means that only one instance of that object can exist. After the assignments `a = None` and `b = None`, it is guaranteed that `a is b` because `None` is a singleton.

In most other circumstances, identity tests are inadvisable and equality tests are preferred. In particular, identity tests should not be used to check constants such as `int` and `str` which aren't guaranteed to be singletons:

```
>>> a = 1000
>>> b = 500
>>> c = b + 500
>>> a is c
False
```

```
>>> a = 'Python'
>>> b = 'Py'
>>> c = b + 'thon'
>>> a is c
False
```

Likewise, new instances of mutable containers are never identical:

```
>>> a = []
>>> b = []
>>> a is b
False
```

In the standard library code, you will see several common patterns for correctly using identity tests:

1) As recommended by [PEP 8](https://peps.python.org/pep-0008/) [https://peps.python.org/pep-0008/], an identity test is the preferred way to check for `None`. This reads like plain English in code and avoids confusion with other objects that may have boolean values that evaluate to false.

2) Detecting optional arguments can be tricky when `None` is a valid input value. In those situations, you can create a singleton sentinel object guaranteed to be distinct from other objects. For example, here is how to implement a method that behaves like `dict.pop()`:

```
_sentinel = object()

def pop(self, key, default=_sentinel):
 if key in self:
 value = self[key]
 del self[key]
 return value
 if default is _sentinel:
 raise KeyError(key)
 return default
```

3) Container implementations sometimes need to augment equality tests with identity tests. This prevents the code from being confused by objects such as `float('NaN')` that are not equal to themselves.

For example, here is the implementation of `collections.abc.Sequence.__contains__()`:

```
def __contains__(self, value):
 for v in self:
 if v is value or v == value:
 return True
 return False
```

## How can a subclass control what data is stored in an immutable instance?

When subclassing an immutable type, override the `__new__()`

method instead of the `__init__()` method. The latter only runs *after* an instance is created, which is too late to alter data in an immutable instance.

All of these immutable classes have a different signature than their parent class:

```
from datetime import date
```

```
class FirstOfMonthDate(date):
 "Always choose the first day of the month"
 def __new__(cls, year, month, day):
 return super().__new__(cls, year, month, 1)
```

```
class NamedInt(int):
 "Allow text names for some numbers"
 xlat = {'zero': 0, 'one': 1, 'ten': 10}
 def __new__(cls, value):
 value = cls.xlat.get(value, value)
 return super().__new__(cls, value)
```

```
class TitleStr(str):
 "Convert str to name suitable for a URL path"
 def __new__(cls, s):
 s = s.lower().replace(' ', '-')
 s = ''.join([c for c in s if c.isalnum() or c == '-'])
 return super().__new__(cls, s)
```

The classes can be used like this:

```
>>> FirstOfMonthDate(2012, 2, 14)
FirstOfMonthDate(2012, 2, 1)
>>> NamedInt('ten')
10
>>> NamedInt(20)
20
>>> TitleStr('Blog: Why Python Rocks')
'blog-why-python-rocks'
```

## How do I cache method calls?

The two principal tools for caching methods are `functools.cached_property()` and `functools.lru_cache()`. The former stores results at the instance level and the latter at the class level.

The *cached\_property* approach only works with methods that do not take any arguments. It does not create a reference to the instance. The cached method result will be kept only as long as the instance is alive.

The advantage is that when an instance is no longer used, the cached method result will be released right away. The disadvantage is that if instances accumulate, so too will the accumulated method results. They can grow without bound.

The *lru\_cache* approach works with methods that have `hashable` arguments. It creates a reference to the instance unless special efforts are made to pass in weak references.

The advantage of the least recently used algorithm is that the cache is bounded by the specified *maxsize*. The disadvantage is that instances are kept alive until they age out of the cache or until the cache is cleared.

This example shows the various techniques:

```
class Weather:
 "Lookup weather information on a government website"

 def __init__(self, station_id):
 self._station_id = station_id
 # The _station_id is private and immutable

 def current_temperature(self):
 "Latest hourly observation"
 # Do not cache this because old results
 # can be out of date.
```

```

@cached_property
def location(self):
 "Return the longitude/latitude coordinates of the station"
 # Result only depends on the station_id

@lru_cache(maxsize=20)
def historic_rainfall(self, date, units='mm'):
 "Rainfall on a given date"
 # Depends on the station_id, date, and units.

```

The above example assumes that the *station\_id* never changes. If the relevant instance attributes are mutable, the *cached\_property* approach can't be made to work because it cannot detect changes to the attributes.

To make the *lru\_cache* approach work when the *station\_id* is mutable, the class needs to define the `__eq__()` and `__hash__()` methods so that the cache can detect relevant attribute updates:

```

class Weather:
 "Example with a mutable station identifier"

 def __init__(self, station_id):
 self.station_id = station_id

 def change_station(self, station_id):
 self.station_id = station_id

 def __eq__(self, other):
 return self.station_id == other.station_id

 def __hash__(self):
 return hash(self.station_id)

@lru_cache(maxsize=20)
def historic_rainfall(self, date, units='cm'):
 "Rainfall on a given date"
 # Depends on the station_id, date, and units.

```

# Modules

## How do I create a .pyc file?

When a module is imported for the first time (or when the source file has changed since the current compiled file was created) a .pyc file containing the compiled code should be created in a `__pycache__` subdirectory of the directory containing the .py file. The .pyc file will have a filename that starts with the same name as the .py file, and ends with .pyc, with a middle component that depends on the particular python binary that created it. (See [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] for details.)

One reason that a .pyc file may not be created is a permissions problem with the directory containing the source file, meaning that the `__pycache__` subdirectory cannot be created. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server.

Unless the `PYTHONDONTWRITEBYTECODE` environment variable is set, creation of a .pyc file is automatic if you're importing a module and Python has the ability (permissions, free space, etc...) to create a `__pycache__` subdirectory and write the compiled module to that subdirectory.

Running Python on a top level script is not considered an import and no .pyc will be created. For example, if you have a top-level module `foo.py` that imports another module `xyz.py`, when you run `foo` (by typing `python foo.py` as a shell command), a .pyc will be created for `xyz` because `xyz` is imported, but no .pyc file will be created for `foo` since `foo.py` isn't being imported.

If you need to create a .pyc file for `foo` – that is, to create a .pyc file for a module that is not imported – you can, using the `py_compile` and `compileall` modules.

The `py_compile` module can manually compile any module. One way is to use the `compile()` function in that module interactively:

```
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the `.pyc` to a `__pycache__` subdirectory in the same location as `foo.py` (or you can override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the `compileall` module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

## How do I find the current module name?

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```
def main():
 print('Running test...')
 ...

if __name__ == '__main__':
 main()
```

## How can I have modules that mutually import each other?

Suppose you have the following modules:

```
foo.py:

from bar import bar_var
foo_var = 1
```

`bar.py:`

```
from foo import foo_var
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports `foo`
- Empty globals for `foo` are created
- `foo` is compiled and starts executing
- `foo` imports `bar`
- Empty globals for `bar` are created
- `bar` is compiled and starts executing
- `bar` imports `foo` (which is a no-op since there already is a module named `foo`)
- The import mechanism tries to read `foo_var` from `foo` globals, to set `bar.foo_var = foo.foo_var`

The last step fails, because Python isn't done with interpreting `foo` yet and the global symbol dictionary for `foo` is still empty.

The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- import statements
- active code (including globals that are initialized from imported values).

Van Rossum doesn't like this approach much because the imports

appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

**`_import_('x.y.z')` returns `<module 'x'>`; how do I get `z`?**

Consider using the convenience function `import_module()` from `importlib` instead:

```
z = importlib.import_module('x.y.z')
```

**When I edit an imported module and reimport it, the changes don't show up. Why does this happen?**

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn't, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force re-reading of a changed module, do this:

```
import importlib
import modname
importlib.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will *not* be updated to use the new class definition. This can result in the following paradoxical behaviour:

```
>>> import importlib
```

```
>>> import cls
>>> c = cls.C() # Create an instance of C
>>> importlib.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C) # isinstance is false?!?
False
```

The nature of the problem is made clear if you print out the “identity” of the class objects:

```
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```

- Why are colons required for the if/while/def/class statements?
- Why does Python allow commas at the end of lists and tuples?

## Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
 x++;
 y--;
z++;
```

Only the `x++` statement is executed if the condition is true, but the indentation leads many to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering as to why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place

the braces. After becoming used to reading and writing code using a particular style, it is normal to feel somewhat uneasy when reading (or being required to write) in a different one.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20–30 lines). 20 lines of Python can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.

## Why am I getting strange results with simple arithmetic operations?

See the next question.

## Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```
>>> 1.2 - 1.0
0.19999999999999996
```

and think it is a bug in Python. It's not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The `float` type in CPython uses a C `double` for storage. A `float` object's value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation

cannot be expressed exactly in binary floating-point. For example, after:

```
>>> x = 1.2
```

the value stored for `x` is a (very good) approximation to the decimal value `1.2`, but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011001100110011
```

which is exactly:

```
1.1999999999999999555910790149937383830547332763671875
```

The typical precision of 53 bits provides Python floats with 15–16 decimal digits of accuracy.

For a fuller explanation, please see the [floating point arithmetic](#) chapter in the Python tutorial.

## Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value `8` to anything else, and in Python, no amount of activity will change the string “eight” to anything else.

## Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it's more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don't know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you'd have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>)`. This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren't explicitly declared global), there has to be some way to tell the interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.

## Why can't I use an assignment in an expression?

Starting in Python 3.8, you can!

Assignment expressions using the walrus operator `:=` assign a variable in an expression:

```
while chunk := fp.read(200):
 print(chunk)
```

See [PEP 572](https://peps.python.org/pep-0572/) [https://peps.python.org/pep-0572/] for more information.

## Why does Python use methods for some functionality (e.g. `list.index()`) but functions for other (e.g. `len(list)`)?

As Guido said:

(a) For some operations, prefix notation just reads better than postfix – prefix (and infix!) operations have a long tradition in mathematics which likes notations where the visuals help the mathematician thinking about a problem. Compare the easy with which we rewrite a formula like  $x*(a+b)$  into  $x*a + x*b$  to the clumsiness of doing the same thing using a raw OO notation.

(b) When I read code that says `len(x)` I *know* that it is asking for the length of something. This tells me two things: the result is an integer, and the argument is some kind of container. To the contrary, when I read `x.len()`, I have to already know that `x` is some kind of container implementing an interface or inheriting from a class that has a standard `len()`. Witness the confusion we occasionally have when a class that is not implementing a mapping has a `get()` or `keys()` method, or something that isn't a file has a `write()` method.

## Why is `join()` a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
", ".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split(", ")
```

is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself

between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.

## How fast are exceptions?

A try/except block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```
try:
 value = mydict[key]
except KeyError:
 mydict[key] = getvalue(key)
 value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn't the case, you coded it like this:

```
if key in mydict:
 value = mydict[key]
else:
 value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.

## Why isn't there a switch or case statement in Python?

You can do this easily enough with a sequence of `if... elif... elif... else`. For literal values, or constants within a namespace, you can also use a `match ... case` statement.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to

functions to call. For example:

```
functions = {'a': function_1,
 'b': function_2,
 'c': self.method_1}
```

```
func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```
class MyVisitor:
 def visit_a(self):
 ...

 def dispatch(self, value):
 method_name = 'visit_' + str(value)
 method = getattr(self, method_name)
 method()
```

It's suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.

## Can't you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is [Stackless Python](https://github.com/stackless-dev/stackless/wiki) [https://github.com/stackless-dev/stackless/wiki], which has a completely redesigned interpreter loop that avoids the C stack.

## Why can't lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally defined function is that you don't need to invent a name for the function – but that's just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!

## Can Python be compiled to machine code, C or some other language?

**Cython** [<https://cython.org/>] compiles a modified version of Python with optional annotations into C extensions. **Nuitka** [<https://www.nuitka.net/>] is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language.

## How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, **CPython**, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The **gc** module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as **Jython** [<https://www.jython.org/>] or **PyPy** [<https://www.pypy.org/>]), however, can rely on a different

mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```
for file in very_long_list_of_files:
 f = open(file)
 c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to *f* closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the **with** statement; this will work regardless of memory management scheme:

```
for file in very_long_list_of_files:
 with open(file) as f:
 c = f.read(1)
```

## Why doesn't CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it's not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for *most* common platforms, not for all of them, and although it is mostly transparent, it isn't completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it's fine to replace the standard `malloc()` and `free()` with versions provided by the GC library, an application embedding Python may want to have its *own* substitute for `malloc()` and `free()`, and may not want Python's. Right now, CPython works with anything that implements

`malloc()` and `free()` properly.

## Why isn't all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.

## Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they're small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can't replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements.

Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.

## How are lists implemented in CPython?

CPython's lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array's length in a list head structure.

This makes indexing a list `a[i]` an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don't require an actual resize.

## How are dictionaries implemented in CPython?

CPython's dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key and a per-process seed; for example, "Python" could hash to -539294296 while "python", a string that differs by a single bit, could hash to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you're storing keys that all have different hash values, this means that dictionaries take constant time –  $O(1)$ , in Big-O notation – to retrieve a key.

## Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can't tell that it was being used as a dictionary key, it can't move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won't be found because its hash value is different. If you tried to look up the old value it wouldn't be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn't work because if you construct a new list with the same value it won't be found; e.g.:

```
mydict = {[1, 2]: '12'}
print(mydict[[1, 2]])
```

would raise a **KeyError** exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using **is**.

- Make a copy when using a list as a key. This doesn't work because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.
- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it's not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a `__eq__()` and a `__hash__()` method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```
class ListWrapper:
 def __init__(self, the_list):
 self.the_list = the_list

 def __eq__(self, other):
 return self.the_list == other.the_list

 def __hash__(self):
 l = self.the_list
 result = 98767 - len(l)*555
 for i, el in enumerate(l):
 try:
 result = result + (hash(el) % 9999999) *
 except Exception:
 result = (result % 7777777) + i * 333
 return result
```

Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if `o1 == o2` (ie `o1.__eq__(o2)` is True) then `hash(o1) == hash(o2)` (ie, `o1.__hash__() == o2.__hash__()`), regardless of whether the

object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of `ListWrapper`, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don't do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.

## Why doesn't `list.sort()` return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won't be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here's how to iterate over the keys of a dictionary in sorted order:

```
for key in sorted(mydict):
 ... # do whatever with mydict[key]...
```

## How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and

`issubclass()` to check whether an instance or a class implements a particular ABC. The `collections.abc` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would. In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `append()` method is expected to add new elements to the end of some internal list; an interface specification cannot test that your `append()` implementation will actually do this correctly, but it’s trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code to make it easily tested. One increasingly popular technique, test-driven development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.

## Why is there no goto?

In the 1970s people realized that unrestricted goto could lead to messy “spaghetti” code that was hard to understand and revise. In a high-level language, it is also unneeded as long as there are ways to branch (in Python, with `if` statements and `or`, `and`, and `if-else` expressions) and loop (with `while` and `for` statements, possibly containing `continue` and `break`).

One can also use exceptions to provide a “structured goto” that works even across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```
class label(Exception): pass # declare a label

try:
 ...
 if condition: raise label() # goto label
 ...
except label: # where to goto
 pass
...
```

This doesn’t allow you to jump into the middle of a loop, but that’s usually considered an abuse of goto anyway. Use sparingly.

## Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```
f = open("/mydir/file.txt") # works fine!
```

If you’re trying to build a pathname for a DOS command, try e.g.

one of

```
dir = r"\this\is\my\dos\dir" "\\ "
dir = r"\this\is\my\dos\dir\ "[:-1]
dir = "\\this\\is\\my\\dos\\dir\\"
```

## Why doesn't Python have a “with” statement for attribute assignments?

Python has a ‘with’ statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some languages have a construct that looks like this:

```
with obj:
 a = 1 # equivalent to obj.a = 1
 total = total + 1 # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it's possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler *always* knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```
def foo(a):
 with a:
 print(x)
```

The snippet assumes that “a” must have a member attribute called “x”. However, there is nothing in Python that tells the interpreter this. What should happen if “a” is, let us say, an integer? If there is

a global variable named “x”, will it be used inside the with block? As you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.

## Why don't generators support the with statement?

For technical reasons, a generator used directly as a context manager would not work correctly. When, as is most common, a generator is used as an iterator run to completion, no closing is needed. When it is, wrap it as “contextlib.closing(generator)” in the ‘with’ statement.

## Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```
if a == b
 print(a)
```

versus

```
if a == b:
 print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.

## Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```
[1, 2, 3,]
('a', 'b', 'c',)
d = {
 "A": [1, 5],
 "B": [6, 7], # last trailing comma is optional but
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```
x = [
 "fee",
 "fie"
 "foo",
 "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source of error.

Allowing the trailing comma may also make programmatic code generation easier.

## General Library Questions

### How do I find a module or application to perform task X?

Check [the Library Reference](#) to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the [Python Package Index](https://pypi.org) [https://pypi.org] or try [Google](https://www.google.com) [https://www.google.com] or another web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

### Where is the `math.py` (`socket.py`, `regex.py`, etc.)

## source file?

If you can't find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like `mathmodule.c`, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:

```
import sys
print(sys.builtin_module_names)
```

## How do I make a Python script executable on Unix?

You need to do two things: the script file's mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the `env` program. Almost all Unix variants support the following, assuming the Python interpreter is

in a directory on the user's **PATH**:

```
#!/usr/bin/env python
```

*Don't* do this for CGI scripts. The **PATH** variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.

Occasionally, a user's environment is so full that the **/usr/bin/env** program fails; or there's no **env** program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```
#!/bin/sh
""" : """
exec python $0 ${1+"$@"}
```

The minor disadvantage is that this defines the script's `__doc__` string. However, you can fix that by adding

```
__doc__ = """...Whatever..."""
```

## Is there a **curses/termcap** package for Python?

For Unix variants: The standard Python source distribution comes with a **curses** module in the **Modules** [<https://github.com/python/cpython/tree/3.11/Modules>] subdirectory, though it's not compiled by default. (Note that this is not available in the Windows distribution – there is no **curses** module for Windows.)

The **curses** module supports basic **curses** features as well as many additional functions from **ncurses** and **SVS** **curses** such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD **curses**, but there don't seem to be any currently maintained OSes that fall into this category.

## Is there an equivalent to C's **onexit()** in Python?

The **atexit** module provides a register function that is similar to C's **onexit()**.

## Why don't my signal handlers work?

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two parameters:

```
def handler(signum, frame):
 ...
```

## Common tasks

### How do I test a Python program or component?

Python comes with two testing frameworks. The **doctest** module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The **unittest** module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```
if __name__ == "__main__":
 main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of function and class behaviours, you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it's surprisingly easy. You can make coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```
if __name__ == "__main__":
 self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

## How do I create documentation from doc strings?

The **pydoc** module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is **epydoc** [<https://epydoc.sourceforge.net/>]. **Sphinx** [<https://www.sphinx-doc.org>] can also include docstring content.

## How do I get a single keypress at a time?

For Unix variants there are several solutions. It's straightforward to do this using **curses**, but **curses** is a fairly large module to learn.

# Threads

## How do I program using threads?

Be sure to use the **threading** module and not the **\_thread** module. The **threading** module builds convenient abstractions on top of the low-level primitives provided by the **\_thread** module.

## None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```
import threading, time

def thread_task(name, n):
 for i in range(n):
 print(name, i)

for i in range(10):
 T = threading.Thread(target=thread_task, args=(str(i), 10))
 T.start()

time.sleep(10) # <-----!
```

But now (on many platforms) the threads don't run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn't start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```
def thread_task(name, n):
 time.sleep(0.001) # <-----!
 for i in range(n):
 print(name, i)

for i in range(10):
 T = threading.Thread(target=thread_task, args=(str(i), 10))
 T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for `time.sleep()`,

it's better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

## How do I parcel out work among a bunch of worker threads?

The easiest way is to use the `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects and has a `.put(obj)` method that adds items to the queue and a `.get()` method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```
import threading, queue, time

The worker thread gets jobs off the queue. When the queue
assumes there will be no more work and exits.
(Realistically workers will run until terminated.)
def worker():
 print('Running worker')
 time.sleep(0.1)
 while True:
 try:
 arg = q.get(block=False)
 except queue.Empty:
 print('Worker', threading.current_thread(),
 'queue empty')
 break
 else:
 print('Worker', threading.current_thread(),
 'running with argument', arg)
```

```

 time.sleep(0.5)

Create queue
q = queue.Queue()

Start a pool of 5 workers
for i in range(5):
 t = threading.Thread(target=worker, name='worker %i' % i)
 t.start()

Begin adding work to the queue
for i in range(50):
 q.put(i)

Give threads time to run
print('Main thread sleeping')
time.sleep(5)

```

When run, this will produce the following output:

```

Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> runni
Worker <Thread(worker 2, started 130283824404752)> runni
Worker <Thread(worker 3, started 130283816012048)> runni
Worker <Thread(worker 4, started 130283807619344)> runni
Worker <Thread(worker 5, started 130283799226640)> runni
Worker <Thread(worker 1, started 130283832797456)> runni
...

```

Consult the module's documentation for more details; the [Queue](#) class provides a featureful interface.

## What kinds of global value mutation are thread-safe?

A [global interpreter lock](#) (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setswitchinterval()`. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren't:

```
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects' `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!

## Can't we get rid of the Global Interpreter Lock?

The [global interpreter lock](#) (GIL) is often seen as a hindrance to Python's deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the "free threading" patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his [python-safethread](https://code.google.com/archive/p/python-safethread) [https://code.google.com/archive/p/python-safethread] project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn't mean that you can't make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The [ProcessPoolExecutor](#) class in the new [concurrent.futures](#) module provides an easy way of doing so; the [multiprocessing](#) module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as [zlib](#) and [hashlib](#) already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn't be able to share objects. Unfortunately, this isn't likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter

state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?

## Input and Output

### How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`; use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+")`, and use `f.truncate(offset)`; `offset` defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

### How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on Windows NTFS volumes, it does not copy [alternate data streams](https://en.wikipedia.org/wiki/NTFS#Alternate_data_stream_(ADS)) [https://en.wikipedia.org/wiki/NTFS#Alternate\_data\_stream\_(ADS)] nor [resource forks](https://en.wikipedia.org/wiki/Resource_fork) [https://en.wikipedia.org/wiki/Resource\_fork] on macOS HFS+ volumes, though both are now rarely used. It also doesn't copy file permissions and metadata, though using `shutil.copy2()` instead will preserve most (though not all) of it.

## How do I read (or write) binary data?

To read or write complex binary data formats, it's best to use the `struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```
import struct

with open(filename, "rb") as f:
 s = f.read(8)
 x, y, z = struct.unpack(">hhl", s)
```

The `'>'` in the format string forces big-endian data; the letter `'h'` reads one “short integer” (2 bytes), and `'l'` reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the `array` module.

### Note

To read and write binary data, it is mandatory to open the file in binary mode (here, passing `"rb"` to `open()`). If you use `"r"` instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

## I can't seem to use `os.read()` on a pipe created with

## os.popen(); why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()` function. Thus, to read  $n$  bytes from a pipe  $p$  created with `os.popen()`, you need to use `p.read(n)`.

## How do I access the serial (RS232) port?

For Win32, OSX, Linux, BSD, Jython, IronPython:

<https://pypi.org/project/pyserial/>

For Unix, see a Usenet post by Mitch Chapman:

[https://groups.google.com/groups?  
selm=34A04430.CF9@ohioee.com](https://groups.google.com/groups?selm=34A04430.CF9@ohioee.com)

## Why doesn't closing sys.stdout (stdin, stderr) really close it?

Python [file objects](#) are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in `open()` function, `f.close()` marks the Python file object as being closed from Python's point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in `f`'s destructor, when `f` becomes garbage.

But `stdin`, `stdout` and `stderr` are treated specially by Python, because of the special status also given to them by C. Running `sys.stdout.close()` marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that's what you really want to do (e.g., you may confuse extension modules trying to do I/O). If it is, use `os.close()`:

```
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.

## Network/Internet Programming

### What WWW tools are there for Python?

See the chapters titled [Internet Protocols and Support](#) and [Internet Data Handling](#) in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

A summary of available frameworks is maintained by Paul Boddie at <https://wiki.python.org/moin/WebProgramming>.

Cameron Laird maintains a useful set of pages about Python web technologies at [https://web.archive.org/web/20210224183619/http://phaseit.net/claird/comp.lang.python/web\\_python](https://web.archive.org/web/20210224183619/http://phaseit.net/claird/comp.lang.python/web_python).

### How can I mimic CGI form submission (METHOD = POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here's a simple example that uses `urllib.request`:

```
#!/usr/local/bin/python

import urllib.request

build the query string
qs = "First=Josephine&MI=Q&Last=Public"

connect and send the server a path
req = urllib.request.urlopen('http://www.some-server.out
```

```
 '/cgi-bin/some-cgi-script',
with req:
 msg, hdrs = req.read(), req.info()
```

Note that in general for percent-encoded POST operations, query strings must be quoted using `urllib.parse.urlencode()`. For example, to send `name=Guy Steele, Jr.:`

```
>>> import urllib.parse
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.'})
'name=Guy+Steele%2C+Jr.'
```

## See also

[HOWTO Fetch Internet Resources Using The urllib Package](#) for extensive examples.

## What module should I use to help with generating HTML?

You can find a collection of useful links on the [Web Programming wiki page](https://wiki.python.org/moin/WebProgramming) [https://wiki.python.org/moin/WebProgramming].

## How do I send mail from a Python script?

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```
import sys, smtplib

fromaddr = input("From: ")
toaddrs = input("To: ").split(',')
print("Enter message, end with ^D:")
msg = ''
while True:
 line = sys.stdin.readline()
 if not line:
```

```
 break
 msg += line

The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()
```

A Unix-only alternative uses `sendmail`. The location of the `sendmail` program varies between systems; sometimes it is `/usr/lib/sendmail`, sometimes `/usr/sbin/sendmail`. The `sendmail` manual page will help you out. Here's some sample code:

```
import os

SENDMAIL = "/usr/sbin/sendmail" # sendmail location
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n") # blank line separating headers from body
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
 print("Sendmail exit status", sts)
```

## How do I avoid blocking in the `connect()` method of a `socket`?

The `select` module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `socket.connect()`, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `socket.connect_ex()` method to avoid creating an exception. It will just return the `errno` value. To poll, you can call `socket.connect_ex()` again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to `select.select()` to check if it's writable.

## Note

The `asyncio` module provides a general purpose single-threaded and concurrent asynchronous library, which can be used for writing non-blocking network code. The third-party `Twisted` [<https://twisted.org/>] library is a popular and feature-rich alternative.

## Databases

### Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as `DBM` and `GDBM` are also included with standard Python. There is also the `sqlite3` module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the [DatabaseProgramming wiki page](https://wiki.python.org/moin/DatabaseProgramming) [<https://wiki.python.org/moin/DatabaseProgramming>] for details.

### How do you implement persistent objects in Python?

The `pickle` library module solves this in a very general way (though you still can't store things like open files, sockets or windows), and the `shelve` library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.

## Mathematics and Numerics

## How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```
import random
random.random()
```

This returns a random floating point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).
- `uniform(a, b)` chooses a floating point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses a random element from a given sequence.
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly.

There's also a `Random` class you can instantiate to create independent multiple random number generators.

  - [How do I find undefined g++ symbols \\_builtin\\_new or \\_pure\\_virtual?](#)
  - [Can I create an object class with some methods implemented in C and others in Python \(e.g. through inheritance\)?](#)

## Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document [Extending and Embedding the Python Interpreter](#).

Most intermediate or advanced Python books will also cover this topic.

## Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.

## Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

[Cython](https://cython.org) [https://cython.org] and its relative [Pyrex](https://www.cosc.canterbury.ac.nz/greg.ewing/python/Pyrex/) [https://www.cosc.canterbury.ac.nz/greg.ewing/python/Pyrex/] are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as [SWIG](https://www.swig.org) [https://www.swig.org], [SIP](https://riverbankcomputing.com/software/sip/intro) [https://riverbankcomputing.com/software/sip/intro], [CXX](https://cxx.sourceforge.net/) [https://cxx.sourceforge.net/], [Boost](https://www.boost.org/libs/python/doc/index.html) [https://www.boost.org/libs/python/doc/index.html], or [Weave](https://github.com/scipy/weave) [https://github.com/scipy/weave] are also alternatives for wrapping C++ libraries.

## How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`.

## How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.

## How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyList_Size()` and `PyList_GetItem()`.

For bytes, `PyBytes_Size()` returns its length and `PyBytes_AsStringAndSize()` provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C's `strlen()` should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use `PyBytes_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called 'abstract' interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like `PySequence_Length()`, `PySequence_GetItem()`, etc. as well as many other useful protocols such as numbers (`PyNumber_Index()` et al.) and mappings in the `PyMapping` APIs.

## How do I use `Py_BuildValue()` to create a tuple of arbitrary length?

You can't. Use `PyTuple_Pack()` instead.

## How do I call an object's method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```
PyObject *
PyObject_CallMethod(PyObject *object, const char *method,
 const char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`ing the return value.

To call, e.g., a file object's “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
 ... an exception occurred ...
}
else {
 Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` *always* wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”.

## How do I catch the output from `PyErr_Print()` (or anything that prints to

## stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `io.StringIO` class:

```
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
... def __init__(self):
... self.data = []
... def write(self, stuff):
... self.data.append(stuff)
...
>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(''.join(sys.stdout.data))
foo
hello world!
```

## How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```
module = PyImport_ImportModule("<modulename>");
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.

## How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading [the “Extending and Embedding” document](#). Realize that for the Python run-time system, there isn't a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see [Writing C is hard; are there any alternatives?](#).

## I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)

## How do I debug an extension?

When using GDB with dynamically loaded extensions, you can't set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue # repeat until your extension is loaded
gdb) finish # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```

## I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don't include the `/usr/lib/python2.x/config/` directory, which contains various files required for compiling Python extensions.

For Red Hat, install the `python-devel` RPM to get the necessary files.

For Debian, run `apt-get install python-dev`.

## How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter's behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn't close your parentheses or triple string quotes), but it gives

you a syntax error message immediately when the input is invalid.

In Python you can use the `codeop` module, which approximates the parser's behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call `PyRun_InteractiveLoop()` (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the `PyOS_ReadlineFunctionPointer()` to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

## How do I find undefined g++ symbols `__builtin_new` or `__pure_virtual`?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change `LINKCC` in the Python `Modules Makefile`), and link your extension module using g++ (e.g., `g++ -shared -o mymodule.so mymodule.o`).

## Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

Yes, you can inherit from built-in classes such as `int`, `list`, `dict`, etc.

The Boost Python Library (BPL, <https://www.boost.org/libs/python/doc/index.html>) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

## How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up *typing* Windows commands into what is referred to as a “Command prompt window”. Usually you can create such a window from your search bar by searching for `cmd`. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\YourName\Projects\Python>
```

depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python *interpreter*. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “py” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `py` and hitting return:

```
C:\Users\YourName> py
```

You should then see something like:

```
Python 3.6.4 (v3.6.4:d48eceb, Dec 19 2017, 06:04:45) [MS
Type "help", "copyright", "credits" or "license" for mor
>>>
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
'HelloHelloHello'
```

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, call the `exit()` function or hold the `Ctrl` key down while you enter a `z`, then hit the “Enter” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as *Start ▸ Programs ▸ Python 3.x ▸ Python (command line)* that results in you seeing the `>>>` prompt in a new window. If so, the window will disappear after you call the `exit()` function or enter the `Ctrl-Z` character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

Now that we know the `py` command is recognized, you can give your Python script to it. You’ll have to give either an absolute or a relative path to the Python script. Let’s say your Python script is located in your desktop and is named `hello.py`, and your command prompt is nicely opened in your home directory so you’re seeing something similar to:

```
C:\Users\YourName>
```

So now you’ll ask the `py` command to give your script to Python by typing `py` followed by your script path:

```
C:\Users\YourName> py Desktop\hello.py
hello
```

## How do I make Python scripts executable?

On Windows, the standard Python installer already associates the `.py` extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (`D:\Program Files\Python\python.exe "%1" %*`). This is enough to make scripts executable from the command prompt as ‘`foo.py`’. If you’d rather be able to execute the script by simple typing ‘`foo`’ with no extension you need to add `.py` to the `PATHEXT` environment variable.

## Why does Python sometimes take so long

## to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.

## How do I make an executable from a Python script?

See [How can I create a stand-alone binary from a Python script?](#) for a list of tools that can be used to make executables.

## Is a \*.pyd file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named `foo.pyd`, then it must have a function `PyInit_foo()`. You can then write Python “import foo”, and Python will search for `foo.pyd` (as well as `foo.py`, `foo.pyc`) and if it finds it, will attempt to call `PyInit_foo()` to initialize it. You do not link your .exe with `foo.lib`, as that would cause Windows to require the DLL to be present.

Note that the search path for `foo.pyd` is `PYTHONPATH`, not the same as the path that Windows uses to search for `foo.dll`. Also, `foo.pyd` need not be present to run your program, whereas if you linked your program with a `dll`, the `dll` is required. Of course, `foo.pyd` is required if you want to say `import foo`. In a `DLL`,

linkage is declared in the source code with `__declspec(dllexport)`. In a `.pyd`, linkage is defined in a list of available functions.

## How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do **not** build Python into your `.exe` file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `pythonNN.dll`; it is typically installed in `C:\Windows\System`. `NN` is the Python version, a number such as "33" for Python 3.3.

You can link to Python in two different ways. Load-time linking means linking against `pythonNN.lib`, while run-time linking means linking against `pythonNN.dll`. (General note: `pythonNN.lib` is the so-called "import lib" corresponding to `pythonNN.dll`. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `pythonNN.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `pythonNN.dll` (that is, Python's C API's) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python's C API.

2. If you use SWIG, it is easy to create a Python "extension module" that will make the app's data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link *into* your `.exe` file (!) You do **not** have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is `leo`, the init function will be called `initleo()`. If you use SWIG shadow classes, as you should, the init function will be called `initleoC()`. This initializes a mostly hidden helper class used by the shadow class.

The reason you can link the C code in step 2 into your `.exe` file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

```
#include <Python.h>
...
Py_Initialize(); // Initialize Python.
initmyAppC(); // Initialize (import) the helper cl
PyRun_SimpleString("import myApp"); // Import the
```

5. There are two problems with Python's C API which will become apparent if you use a compiler other than MSVC, the compiler used to build `pythonNN.dll`.

**Problem 1:** The so-called "Very High Level" functions that take `FILE *` arguments will not work in a multi-compiler environment because each compiler's notion of a `struct FILE` will be different. From an implementation standpoint these are very low level functions.

**Problem 2:** SWIG generates the following code when generating wrappers to void functions:

```
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

Alas, `Py_None` is a macro that expands to a reference to a complex data structure called `_Py_NoneStruct` inside

pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

```
return Py_BuildValue("");
```

It may be possible to use SWIG's `%typemap` command to make the change automatically, though I have not been able to get this to work (I'm a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app's windowing system. Rather, you (or the `wxPythonWindow` class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python's i/o to `_any_` object that supports read and write, so all you need is a Python object (defined in your extension module) that contains `read()` and `write()` methods.

## How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, [PEP 8](https://peps.python.org/pep-0008/) [https://peps.python.org/pep-0008/], recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take *Tools* ▶ *Options* ▶ *Tabs*, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

Python raises `IndentationError` or `TabError` if mixed tabs and spaces are causing problems in leading whitespace. You may also run the `tabnanny` module to check a directory tree in batch mode.

## How do I check for a keypress without blocking?

Use the `msvcrt` module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.

## How do I solve the missing `api-ms-win-crt-runtime-l1-1-0.dll` error?

This can occur on Python 3.5 and later when using Windows 8.1 or earlier without all updates having been installed. First ensure your operating system is supported and is up to date, and if that does not resolve the issue, visit the [Microsoft support page](https://support.microsoft.com/en-us/help/3118401/) [https://support.microsoft.com/en-us/help/3118401/] for guidance on manually installing the C Runtime update.

    - [I can't get key bindings to work in Tkinter: why?](#)

## General GUI Questions

### What GUI toolkits exist for Python?

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called [tkinter](#). This is probably the easiest to install (since it comes included with most [binary distributions](#) [<https://www.python.org/downloads/>] of Python) and use. For more info about Tk, including pointers to the source, see the [Tcl/Tk home page](#) [<https://www.tcl.tk>]. Tcl/Tk is fully portable to the macOS, Windows, and Unix platforms.

Depending on what platform(s) you are aiming at, there are also several alternatives. A [list of cross-platform](#) [[https://wiki.python.org/moin/GuiProgramming#Cross-Platform\\_Frameworks](https://wiki.python.org/moin/GuiProgramming#Cross-Platform_Frameworks)] and [platform-specific](#) [[https://wiki.python.org/moin/GuiProgramming#Platform-specific\\_Frameworks](https://wiki.python.org/moin/GuiProgramming#Platform-specific_Frameworks)] GUI frameworks can be found on the python wiki.

## Tkinter questions

## How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the **TCL\_LIBRARY** and **TK\_LIBRARY** environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (<https://tix.sourceforge.net/>).

Build Tix with SAM enabled, perform the appropriate call to **Tclsam\_init()**, etc. inside Python's `Modules/tkappinit.c`, and link with `libtclsam` and `libtkSAM` (you might include the Tix libraries as well).

## Can I have Tk events handled while waiting for I/O?

On platforms other than Windows, yes, and you don't even need threads! But you'll have to restructure your I/O code a bit. Tk has the equivalent of Xt's **XtAddInput()** call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. See [File Handlers](#).

## I can't get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the **bind()** method don't get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn't have "keyboard focus". Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the `takefocus` option).

# “Why is Python Installed on my Computer?” FAQ

## What is Python?

Python is a programming language. It's used for many different applications. It's used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it's also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the [Beginner's Guide to Python](https://wiki.python.org/moin/BeginnersGuide) [https://wiki.python.org/moin/BeginnersGuide].

## Why is Python installed on my machine?

If you find Python installed on your system but don't remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you'll have to figure out who's been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we're aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq's administrative tools are written in Python.
- Many Unix-compatible operating systems, such as macOS and some Linux distributions, have Python installed by default; it's included in the base installation.

# Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.

# Glossary

>>>

The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

...

Can refer to:

- The default Python prompt of the interactive shell when entering the code for an indented code block, when within a pair of matching left and right delimiters (parentheses, square brackets, curly braces or triple quotes), or after specifying a decorator.
- The [Ellipsis](#) built-in constant.

## 2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as [lib2to3](#); a standalone entry point is provided as `Tools/scripts/2to3`. See [2to3 — Automated Python 2 to 3 code translation](#).

## abstract base class

Abstract base classes complement [duck-typing](#) by providing a way to define interfaces when other techniques like [hasattr\(\)](#) would be clumsy or subtly wrong (for example with [magic methods](#)). ABCs introduce virtual subclasses, which are classes that don't inherit from a class but are still recognized by [isinstance\(\)](#) and [issubclass\(\)](#); see the [abc](#) module documentation. Python comes with many built-

in ABCs for data structures (in the `collections.abc` module), numbers (in the `numbers` module), streams (in the `io` module), import finders and loaders (in the `importlib.abc` module). You can create your own ABCs with the `abc` module.

## annotation

A label associated with a variable, a class attribute or a function parameter or return value, used by convention as a [type hint](#).

Annotations of local variables cannot be accessed at runtime, but annotations of global variables, class attributes, and functions are stored in the `__annotations__` special attribute of modules, classes, and functions, respectively.

See [variable annotation](#), [function annotation](#), [PEP 484](#) [<https://peps.python.org/pep-0484/>] and [PEP 526](#) [<https://peps.python.org/pep-0526/>], which describe this functionality. Also see [Annotations Best Practices](#) for best practices on working with annotations.

## argument

A value passed to a [function](#) (or [method](#)) when calling the function. There are two kinds of argument:

- *keyword argument*: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, `3` and `5` are both keyword arguments in the following calls to `complex()`:

```
complex(real=3, imag=5)
complex(**{'real': 3, 'imag': 5})
```

- *positional argument*: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an [iterable](#) preceded by `*`. For example, `3` and `5` are both positional arguments in the following

calls:

```
complex(3, 5)
complex(*(3, 5))
```

Arguments are assigned to the named local variables in a function body. See the [Calls](#) section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the [parameter](#) glossary entry, the FAQ question on [the difference between arguments and parameters](#), and [PEP 362](#) [<https://peps.python.org/pep-0362/>].

## asynchronous context manager

An object which controls the environment seen in an [async with](#) statement by defining `__aenter__()` and `__aexit__()` methods. Introduced by [PEP 492](#) [<https://peps.python.org/pep-0492/>].

## asynchronous generator

A function which returns an [asynchronous generator iterator](#). It looks like a coroutine function defined with `async def` except that it contains `yield` expressions for producing a series of values usable in an `async for` loop.

Usually refers to an asynchronous generator function, but may refer to an *asynchronous generator iterator* in some contexts. In cases where the intended meaning isn't clear, using the full terms avoids ambiguity.

An asynchronous generator function may contain `await` expressions as well as `async for`, and `async with` statements.

## asynchronous generator iterator

An object created by a [asynchronous generator](#) function.

This is an [asynchronous iterator](#) which when called using the

`__anext__()` method returns an awaitable object which will execute the body of the asynchronous generator function until the next `yield` expression.

Each `yield` temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the *asynchronous generator iterator* effectively resumes with another awaitable returned by `__anext__()`, it picks up where it left off. See [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/] and [PEP 525](https://peps.python.org/pep-0525/) [https://peps.python.org/pep-0525/].

## asynchronous iterable

An object, that can be used in an `async for` statement. Must return an *asynchronous iterator* from its `__aiter__()` method. Introduced by [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## asynchronous iterator

An object that implements the `__aiter__()` and `__anext__()` methods. `__anext__` must return an *awaitable* object. `async for` resolves the awaitables returned by an asynchronous iterator's `__anext__()` method until it raises a `StopAsyncIteration` exception. Introduced by [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## attribute

A value associated with an object which is usually referenced by name using dotted expressions. For example, if an object *o* has an attribute *a* it would be referenced as *o.a*.

It is possible to give an object an attribute whose name is not an identifier as defined by [Identifiers and keywords](#), for example using `setattr()`, if the object allows it. Such an attribute will not be accessible using a dotted expression, and would instead need to be retrieved with `getattr()`.

## awaitable

An object that can be used in an `await` expression. Can be a *coroutine* or an object with an `__await__()` method. See

also [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## BDFL

Benevolent Dictator For Life, a.k.a. [Guido van Rossum](https://gvanrossum.github.io/) [https://gvanrossum.github.io/], Python's creator.

## binary file

A [file object](#) able to read and write [bytes-like objects](#). Examples of binary files are files opened in binary mode ('rb', 'wb' or 'rb+'), `sys.stdin.buffer`, `sys.stdout.buffer`, and instances of `io.BytesIO` and `gzip.GzipFile`.

See also [text file](#) for a file object able to read and write `str` objects.

## borrowed reference

In Python's C API, a borrowed reference is a reference to an object. It does not modify the object reference count. It becomes a dangling pointer if the object is destroyed. For example, a garbage collection can remove the last [strong reference](#) to the object and so destroy it.

Calling `Py_INCREF()` on the [borrowed reference](#) is recommended to convert it to a [strong reference](#) in-place, except when the object cannot be destroyed before the last usage of the borrowed reference. The `Py_NewRef()` function can be used to create a new [strong reference](#).

## bytes-like object

An object that supports the [Buffer Protocol](#) and can export a C-contiguous buffer. This includes all `bytes`, `bytearray`, and `array.array` objects, as well as many common `memoryview` objects. Bytes-like objects can be used for various operations that work with binary data; these include compression, saving to a binary file, and sending over a socket.

Some operations need the binary data to be mutable. The documentation often refers to these as “read-write bytes-like

objects”. Example mutable buffer objects include [bytearray](#) and a [memoryview](#) of a [bytearray](#). Other operations require the binary data to be stored in immutable objects (“read-only bytes-like objects”); examples of these include [bytes](#) and a [memoryview](#) of a [bytes](#) object.

## bytecode

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a [virtual machine](#) that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for [the dis module](#).

## callable

A callable is an object that can be called, possibly with a set of arguments (see [argument](#)), with the following syntax:

```
callable(argument1, argument2, argumentN)
```

A [function](#), and by extension a [method](#), is a callable. An instance of a class that implements the `__call__()` method is also a callable.

## callback

A subroutine function which is passed as an argument to be executed at some point in the future.

## class

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

## class variable

A variable defined in a class and intended to be modified only at class level (i.e., not in an instance of the class).

## complex number

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of  $-1$ ), often written  $i$  in mathematics or  $j$  in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a  $j$  suffix, e.g.,  $3+1j$ . To get access to complex equivalents of the `math` module, use `cmath`. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

## context manager

An object which controls the environment seen in a `with` statement by defining `__enter__()` and `__exit__()` methods. See [PEP 343](https://peps.python.org/pep-0343/) [https://peps.python.org/pep-0343/].

## context variable

A variable which can have different values depending on its context. This is similar to Thread-Local Storage in which each execution thread may have a different value for a variable. However, with context variables, there may be several contexts in one execution thread and the main usage for context variables is to keep track of variables in concurrent asynchronous tasks. See `contextvars`.

## contiguous

A buffer is considered contiguous exactly if it is either C-*contiguous* or Fortran *contiguous*. Zero-dimensional buffers are C and Fortran contiguous. In one-dimensional arrays, the items must be laid out in memory next to each other, in order of increasing indexes starting from zero. In multidimensional C-contiguous arrays, the last index varies the fastest when visiting items in order of memory address. However, in

Fortran contiguous arrays, the first index varies the fastest.

## coroutine

Coroutines are a more generalized form of subroutines. Subroutines are entered at one point and exited at another point. Coroutines can be entered, exited, and resumed at many different points. They can be implemented with the `async def` statement. See also [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## coroutine function

A function which returns a `coroutine` object. A coroutine function may be defined with the `async def` statement, and may contain `await`, `async for`, and `async with` keywords. These were introduced by [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/].

## CPython

The canonical implementation of the Python programming language, as distributed on [python.org](https://www.python.org) [https://www.python.org]. The term “CPython” is used when necessary to distinguish this implementation from others such as Jython or IronPython.

## decorator

A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```
def f(arg):
 ...
f = staticmethod(f)

@staticmethod
def f(arg):
```

...

The same concept exists for classes, but is less commonly used there. See the documentation for [function definitions](#) and [class definitions](#) for more about decorators.

## descriptor

Any object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors' methods, see [Implementing Descriptors](#) or the [Descriptor How To Guide](#).

## dictionary

An associative array, where arbitrary keys are mapped to values. The keys can be any object with `__hash__()` and `__eq__()` methods. Called a hash in Perl.

## dictionary comprehension

A compact way to process all or part of the elements in an iterable and return a dictionary with the results. `results = {n: n ** 2 for n in range(10)}` generates a dictionary containing key `n` mapped to value `n ** 2`. See [Displays for lists, sets and dictionaries](#).

## dictionary view

The objects returned from `dict.keys()`, `dict.values()`, and `dict.items()` are called dictionary views. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes. To force the dictionary view to become a full list use `list(dictview)`. See [Dictionary](#)

[view objects.](#)

## **docstring**

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

## **duck-typing**

A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with [abstract base classes](#).) Instead, it typically employs `hasattr()` tests or [EAFP](#) programming.

## **EAFP**

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the [LBYL](#) style common to many other languages such as C.

## **expression**

A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also [statements](#) which cannot be used as expressions, such as `while`. Assignments are also statements,

not expressions.

## extension module

A module written in C or C++, using Python's C API to interact with the core and with user code.

## f-string

String literals prefixed with `'f'` or `'F'` are commonly called “f-strings” which is short for [formatted string literals](#). See also [PEP 498](https://peps.python.org/pep-0498/) [https://peps.python.org/pep-0498/].

## file object

An object exposing a file-oriented API (with methods such as `read()` or `write()`) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called *file-like objects* or *streams*.

There are actually three categories of file objects: raw [binary files](#), buffered [binary files](#) and [text files](#). Their interfaces are defined in the `io` module. The canonical way to create a file object is by using the `open()` function.

## file-like object

A synonym for [file object](#).

## filesystem encoding and error handler

Encoding and error handler used by Python to decode bytes from the operating system and encode Unicode to the operating system.

The filesystem encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions can raise [UnicodeError](#).

The `sys.getfilesystemencoding()` and `sys.getfilesystemencodeerrors()` functions can be

used to get the filesystem encoding and error handler.

The [filesystem encoding and error handler](#) are configured at Python startup by the `PyConfig_Read()` function: see [filesystem\\_encoding](#) and [filesystem\\_errors](#) members of `PyConfig`.

See also the [locale encoding](#).

## finder

An object that tries to find the [loader](#) for a module that is being imported.

Since Python 3.3, there are two types of finder: [meta path finders](#) for use with `sys.meta_path`, and [path entry finders](#) for use with `sys.path_hooks`.

See [PEP 302](#) [<https://peps.python.org/pep-0302/>], [PEP 420](#) [<https://peps.python.org/pep-0420/>] and [PEP 451](#) [<https://peps.python.org/pep-0451/>] for much more detail.

## floor division

Mathematical division that rounds down to nearest integer.

The floor division operator is `//`. For example, the expression `11 // 4` evaluates to `2` in contrast to the `2.75` returned by float true division. Note that `(-11) // 4` is `-3` because that is `-2.75` rounded *downward*. See [PEP 238](#) [<https://peps.python.org/pep-0238/>].

## function

A series of statements which returns some value to a caller. It can also be passed zero or more [arguments](#) which may be used in the execution of the body. See also [parameter](#), [method](#), and the [Function definitions](#) section.

## function annotation

An [annotation](#) of a function parameter or return value.

Function annotations are usually used for [type hints](#): for example, this function is expected to take two `int`

arguments and is also expected to have an `int` return value:

```
def sum_two_numbers(a: int, b: int) -> int:
 return a + b
```

Function annotation syntax is explained in section [Function definitions](#).

See [variable annotation](#) and [PEP 484](#) [<https://peps.python.org/pep-0484/>], which describe this functionality. Also see [Annotations Best Practices](#) for best practices on working with annotations.

## `__future__`

A [future statement](#), `from __future__ import <feature>`, directs the compiler to compile the current module using syntax or semantics that will become standard in a future release of Python. The `__future__` module documents the possible values of *feature*. By importing this module and evaluating its variables, you can see when a new feature was first added to the language and when it will (or did) become the default:

```
>>> import __future__
>>> __future__.division
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha',
```

## garbage collection

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles. The garbage collector can be controlled using the `gc` module.

## generator

A function which returns a [generator iterator](#). It looks like a normal function except that it contains `yield` expressions for producing a series of values usable in a for-loop or that can be retrieved one at a time with the `next()` function.

Usually refers to a generator function, but may refer to a *generator iterator* in some contexts. In cases where the intended meaning isn't clear, using the full terms avoids ambiguity.

## generator iterator

An object created by a [generator](#) function.

Each [yield](#) temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the *generator iterator* resumes, it picks up where it left off (in contrast to functions which start fresh on every invocation).

## generator expression

An expression that returns an iterator. It looks like a normal expression followed by a **for** clause defining a loop variable, range, and an optional **if** clause. The combined expression generates values for an enclosing function:

```
>>> sum(i*i for i in range(10)) # sum of sq
285
```

## generic function

A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the [single dispatch](#) glossary entry, the [functools.singledispatch\(\)](#) decorator, and [PEP 443](#) [<https://peps.python.org/pep-0443/>].

## generic type

A [type](#) that can be parameterized; typically a [container class](#) such as [list](#) or [dict](#). Used for [type hints](#) and [annotations](#).

For more details, see [generic alias types](#), [PEP 483](#) [<https://peps.python.org/pep-0483/>], [PEP 484](#) [<https://peps.python.org/pep-0484/>], [PEP 585](#) [<https://peps.python.org/pep-0585/>], and the

[typing](#) module.

## GIL

See [global interpreter lock](#).

## global interpreter lock

The mechanism used by the [CPython](#) interpreter to assure that only one thread executes Python [bytecode](#) at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as [dict](#)) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore costlier to maintain.

## hash-based pyc

A bytecode cache file that uses the hash rather than the last-modified time of the corresponding source file to determine its validity. See [Cached bytecode invalidation](#).

## hashable

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a

set member, because these data structures use the hash value internally.

Most of Python's immutable built-in objects are hashable; mutable containers (such as lists or dictionaries) are not; immutable containers (such as tuples and frozensets) are only hashable if their elements are hashable. Objects which are instances of user-defined classes are hashable by default. They all compare unequal (except with themselves), and their hash value is derived from their `id()`.

## **IDLE**

An Integrated Development and Learning Environment for Python. **IDLE** is a basic editor and interpreter environment which ships with the standard distribution of Python.

## **immutable**

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

## **import path**

A list of locations (or **path entries**) that are searched by the **path based finder** for modules to import. During import, this list of locations usually comes from **sys.path**, but for subpackages it may also come from the parent package's `__path__` attribute.

## **importing**

The process by which Python code in one module is made available to Python code in another module.

## **importer**

An object that both finds and loads a module; both a **finder** and **loader** object.

## interactive

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer's main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`).

## interpreted

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also [interactive](#).

## interpreter shutdown

When asked to shut down, the Python interpreter enters a special phase where it gradually releases all allocated resources, such as modules and various critical internal structures. It also makes several calls to the [garbage collector](#). This can trigger the execution of code in user-defined destructors or weakref callbacks. Code executed during the shutdown phase can encounter various exceptions as the resources it relies on may not function anymore (common examples are library modules or the warnings machinery).

The main reason for interpreter shutdown is that the `__main__` module or the script being run has finished executing.

## iterable

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as [list](#), [str](#), and [tuple](#)) and some non-sequence types like [dict](#), [file objects](#), and objects of any classes you define with

an `__iter__()` method or with a `__getitem__()` method that implements [sequence](#) semantics.

Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, ...). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also [iterator](#), [sequence](#), and [generator](#).

## iterator

An object representing a stream of data. Repeated calls to the iterator's `__next__()` method (or passing it to the built-in function `next()`) return successive items in the stream. When no more data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `__next__()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in [Iterator Types](#).

**CPython implementation detail:** CPython does not consistently apply the requirement that an iterator define `__iter__()`.

## key function

A key function or collation function is a callable that returns

a value used for sorting or ordering. For example, `locale.strxfrm()` is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include `min()`, `max()`, `sorted()`, `list.sort()`, `heapq.merge()`, `heapq.nsmallest()`, `heapq.nlargest()`, and `itertools.groupby()`.

There are several ways to create a key function. For example, the `str.lower()` method can serve as a key function for case insensitive sorts. Alternatively, a key function can be built from a `lambda` expression such as `lambda r: (r[0], r[2])`. Also, `operator.attrgetter()`, `operator.itemgetter()`, and `operator.methodcaller()` are three key function constructors. See the [Sorting HOW TO](#) for examples of how to create and use key functions.

## keyword argument

See [argument](#).

## lambda

An anonymous inline function consisting of a single [expression](#) which is evaluated when the function is called. The syntax to create a lambda function is `lambda [parameters]: expression`

## LBYL

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the [EAFP](#) approach and is characterized by the presence of many `if` statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes `key` from `mapping` after the test, but before the lookup. This

issue can be solved with locks or by using the EAFP approach.

## locale encoding

On Unix, it is the encoding of the LC\_CTYPE locale. It can be set with `locale.setlocale(locale.LC_CTYPE, new_locale)`.

On Windows, it is the ANSI code page (ex: "cp1252").

On Android and VxWorks, Python uses "utf-8" as the locale encoding.

`locale.getencoding()` can be used to get the locale encoding.

See also the [filesystem encoding and error handler](#).

## list

A built-in Python [sequence](#). Despite its name it is more akin to an array in other languages than to a linked list since access to elements is  $O(1)$ .

## list comprehension

A compact way to process all or part of the elements in a sequence and return a list with the results. `result = [{: #04x} '.format(x) for x in range(256) if x % 2 == 0]` generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The `if` clause is optional. If omitted, all elements in `range(256)` are processed.

## loader

An object that loads a module. It must define a method named `load_module()`. A loader is typically returned by a [finder](#). See [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] for details and `importlib.abc.Loader` for an [abstract base class](#).

## magic method

An informal synonym for [special method](#).

## mapping

A container object that supports arbitrary key lookups and implements the methods specified in the `collections.abc.Mapping` or `collections.abc.MutableMapping` abstract base classes. Examples include `dict`, `collections.defaultdict`, `collections.OrderedDict` and `collections.Counter`.

## meta path finder

A `finder` returned by a search of `sys.meta_path`. Meta path finders are related to, but different from `path entry finders`.

See `importlib.abc.MetaPathFinder` for the methods that meta path finders implement.

## metaclass

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in [Metaclasses](#).

## method

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first `argument` (which is usually called `self`). See [function](#) and [nested scope](#).

## method resolution order

Method Resolution Order is the order in which base classes are searched for a member during lookup. See [The Python 2.3](#)

**Method Resolution Order** [<https://www.python.org/download/releases/2.3/mro/>] for details of the algorithm used by the Python interpreter since the 2.3 release.

## module

An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of [importing](#).

See also [package](#).

## module spec

A namespace containing the import-related information used to load a module. An instance of [importlib.machinery.ModuleSpec](#).

## MRO

See [method resolution order](#).

## mutable

Mutable objects can change their value but keep their [id\(\)](#). See also [immutable](#).

## named tuple

The term “named tuple” applies to any type or class that inherits from tuple and whose indexable elements are also accessible using named attributes. The type or class may have other features as well.

Several built-in types are named tuples, including the values returned by [time.localtime\(\)](#) and [os.stat\(\)](#). Another example is [sys.float\\_info](#):

```
>>> sys.float_info[1] # indexed a
1024
>>> sys.float_info.max_exp # named fie
1024
>>> isinstance(sys.float_info, tuple) # kind of t
```

True

Some named tuples are built-in types (such as the above examples). Alternatively, a named tuple can be created from a regular class definition that inherits from `tuple` and that defines named fields. Such a class can be written by hand or it can be created with the factory function `collections.namedtuple()`. The latter technique also adds some extra methods that may not be found in hand-written or built-in named tuples.

## namespace

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `builtins.open` and `os.open()` are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.islice()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.

## namespace package

A [PEP 420](https://peps.python.org/pep-0420/) [https://peps.python.org/pep-0420/] `package` which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a `regular package` because they have no `__init__.py` file.

See also [module](#).

## nested scope

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the

innermost scope. Likewise, global variables read and write to the global namespace. The `nonlocal` allows writing to outer scopes.

## new-style class

Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python's newer, versatile features like `__slots__`, descriptors, properties, `__getattr__()`, class methods, and static methods.

## object

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any [new-style class](#).

## package

A Python [module](#) which can contain submodules or recursively, subpackages. Technically, a package is a Python module with a `__path__` attribute.

See also [regular package](#) and [namespace package](#).

## parameter

A named entity in a [function](#) (or method) definition that specifies an [argument](#) (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- *positional-or-keyword*: specifies an argument that can be passed either [positionally](#) or as a [keyword argument](#). This is the default kind of parameter, for example *foo* and *bar* in the following:

```
def func(foo, bar=None): ...
```

- *positional-only*: specifies an argument that can be supplied only by position. Positional-only parameters can be defined by including a `/` character in the parameter list of the function definition after them, for example *posonly1* and *posonly2* in the following:

```
def func(posonly1, posonly2, /, positional_or_k
```

- *keyword-only*: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare `*` in the parameter list of the function definition before them, for example *kw\_only1* and *kw\_only2* in the following:

```
def func(arg, *, kw_only1, kw_only2): ...
```

- *var-positional*: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `*`, for example *args* in the following:

```
def func(*args, **kwargs): ...
```

- *var-keyword*: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `**`, for example *kwargs* in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the [argument](#) glossary entry, the FAQ question on [the difference between arguments and parameters](#), the [inspect.Parameter](#) class, the [Function definitions](#) section, and [PEP 362](#) [<https://peps.python.org/pep-0362/>].

## path entry

A single location on the [import path](#) which the [path based finder](#) consults to find modules for importing.

## path entry finder

A [finder](#) returned by a callable on [sys.path\\_hooks](#) (i.e. a

[path entry hook](#)) which knows how to locate modules given a [path entry](#).

See [importlib.abc.PathEntryFinder](#) for the methods that path entry finders implement.

## path entry hook

A callable on the `sys.path_hook` list which returns a [path entry finder](#) if it knows how to find modules on a specific [path entry](#).

## path based finder

One of the default [meta path finders](#) which searches an [import path](#) for modules.

## path-like object

An object representing a file system path. A path-like object is either a `str` or `bytes` object representing a path, or an object implementing the `os.PathLike` protocol. An object that supports the `os.PathLike` protocol can be converted to a `str` or `bytes` file system path by calling the `os.fspath()` function; `os.fsdecode()` and `os.fsencode()` can be used to guarantee a `str` or `bytes` result instead, respectively. Introduced by [PEP 519](#) [<https://peps.python.org/pep-0519/>].

## PEP

Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python or its processes or environment. PEPs should provide a concise technical specification and a rationale for proposed features.

PEPs are intended to be the primary mechanisms for proposing major new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

See [PEP 1](https://peps.python.org/pep-0001/) [https://peps.python.org/pep-0001/].

## portion

A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in [PEP 420](https://peps.python.org/pep-0420/) [https://peps.python.org/pep-0420/].

## positional argument

See [argument](#).

## provisional API

A provisional API is one which has been deliberately excluded from the standard library's backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a “solution of last resort” - every attempt will still be made to find a backwards compatible resolution to any identified problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See [PEP 411](https://peps.python.org/pep-0411/) [https://peps.python.org/pep-0411/] for more details.

## provisional package

See [provisional API](#).

## Python 3000

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

## Pythonic

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a **for** statement. Many other languages don't have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```
for i in range(len(food)):
 print(food[i])
```

As opposed to the cleaner, Pythonic method:

```
for piece in food:
 print(piece)
```

## qualified name

A dotted name showing the “path” from a module’s global scope to a class, function or method defined in that module, as defined in **PEP 3155** [<https://peps.python.org/pep-3155/>]. For top-level functions and classes, the qualified name is the same as the object’s name:

```
>>> class C:
... class D:
... def meth(self):
... pass
...
>>> C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

## reference count

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. Programmers can call the `sys.getrefcount()` function to return the reference count for a particular object.

## regular package

A traditional [package](#), such as a directory containing an `__init__.py` file.

See also [namespace package](#).

## `__slots__`

A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

## sequence

An [iterable](#) which supports efficient element access using integer indices via the `__getitem__()` special method and defines a `__len__()` method that returns the length of the sequence. Some built-in sequence types are [list](#), [str](#), [tuple](#), and [bytes](#). Note that [dict](#) also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary [immutable](#) keys rather than integers.

The `collections.abc.Sequence` abstract base class defines a much richer interface that goes beyond just `__getitem__()` and `__len__()`, adding `count()`, `index()`, `__contains__()`, and `__reversed__()`.

Types that implement this expanded interface can be registered explicitly using `register()`.

## set comprehension

A compact way to process all or part of the elements in an iterable and return a set with the results. `results = {c for c in 'abracadabra' if c not in 'abc'}` generates the set of strings `{'r', 'd'}`. See [Displays for lists, sets and dictionaries](#).

## single dispatch

A form of [generic function](#) dispatch where the implementation is chosen based on the type of a single argument.

## slice

An object usually containing a portion of a [sequence](#). A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses [slice](#) objects internally.

## special method

A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in [Special method names](#).

## statement

A statement is part of a suite (a “block” of code). A statement is either an [expression](#) or one of several constructs with a keyword, such as `if`, `while` or `for`.

## strong reference

In Python’s C API, a strong reference is a reference to an object which increments the object’s reference count when it is created and decrements the object’s reference count when it is deleted.

The `Py_NewRef()` function can be used to create a strong reference to an object. Usually, the `Py_DECREF()` function must be called on the strong reference before exiting the scope of the strong reference, to avoid leaking one reference.

See also [borrowed reference](#).

## text encoding

A string in Python is a sequence of Unicode code points (in range U+0000–U+10FFFF). To store or transfer a string, it needs to be serialized as a sequence of bytes.

Serializing a string into a sequence of bytes is known as “encoding”, and recreating the string from the sequence of bytes is known as “decoding”.

There are a variety of different text serialization [codecs](#), which are collectively referred to as “text encodings”.

## text file

A [file object](#) able to read and write `str` objects. Often, a text file actually accesses a byte-oriented datastream and handles the [text encoding](#) automatically. Examples of text files are files opened in text mode (`'r'` or `'w'`), `sys.stdin`, `sys.stdout`, and instances of `io.StringIO`.

See also [binary file](#) for a file object able to read and write [bytes-like objects](#).

## triple-quoted string

A string which is bound by three instances of either a quotation mark (") or an apostrophe ('). While they don't provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

## type

The type of a Python object determines what kind of object it is; every object has a type. An object's type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

## type alias

A synonym for a type, created by assigning the type to an identifier.

Type aliases are useful for simplifying [type hints](#). For example:

```
def remove_gray_shades(
 colors: list[tuple[int, int, int]]) -> list:
 pass
```

could be made more readable like this:

```
Color = tuple[int, int, int]

def remove_gray_shades(colors: list[Color]) -> list:
 pass
```

See [typing](#) and [PEP 484](#) [<https://peps.python.org/pep-0484/>], which describe this functionality.

## type hint

An [annotation](#) that specifies the expected type for a variable, a class attribute, or a function parameter or return value.

Type hints are optional and are not enforced by Python but they are useful to static type analysis tools, and aid IDEs with code completion and refactoring.

Type hints of global variables, class attributes, and functions, but not local variables, can be accessed using [typing.get\\_type\\_hints\(\)](#).

See [typing](#) and [PEP 484](#) [<https://peps.python.org/pep-0484/>], which describe this functionality.

## universal newlines

A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention `'\n'`, the Windows convention `'\r\n'`, and the old Macintosh convention `'\r'`. See [PEP 278](https://peps.python.org/pep-0278/) [https://peps.python.org/pep-0278/] and [PEP 3116](https://peps.python.org/pep-3116/) [https://peps.python.org/pep-3116/], as well as `bytes.splitlines()` for an additional use.

## variable annotation

An [annotation](#) of a variable or a class attribute.

When annotating a variable or a class attribute, assignment is optional:

```
class C:
 field: 'annotation'
```

Variable annotations are usually used for [type hints](#): for example this variable is expected to take `int` values:

```
count: int = 0
```

Variable annotation syntax is explained in section [Annotated assignment statements](#).

See [function annotation](#), [PEP 484](https://peps.python.org/pep-0484/) [https://peps.python.org/pep-0484/] and [PEP 526](https://peps.python.org/pep-0526/) [https://peps.python.org/pep-0526/], which describe this functionality. Also see [Annotations Best Practices](#) for best practices on working with annotations.

## virtual environment

A cooperatively isolated runtime environment that allows Python users and applications to install and upgrade Python distribution packages without interfering with the behaviour of other Python applications running on the same system.

See also [venv](#).

## virtual machine

A computer defined entirely in software. Python's virtual machine executes the [bytecode](#) emitted by the bytecode

compiler.

## **Zen of Python**

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing “`import this`” at the interactive prompt.

# About these documents

These documents are generated from [reStructuredText](https://docutils.sourceforge.io/rst.html) [https://docutils.sourceforge.io/rst.html] sources by [Sphinx](https://www.sphinx-doc.org/) [https://www.sphinx-doc.org/], a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the [Dealing with Bugs](#) page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the [Docutils](https://docutils.sourceforge.io/) [https://docutils.sourceforge.io/] project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

## Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See [Misc/ACKS](https://github.com/python/cpython/tree/3.11/Misc/ACKS) [https://github.com/python/cpython/tree/3.11/Misc/ACKS] in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!

# Dealing with Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

It can be sometimes faster to fix bugs yourself and contribute patches to Python as it streamlines the process and involves less people. Learn how to [contribute](#).

## Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please submit a bug report on the [tracker](#). If you have a suggestion on how to fix it, include that as well.

You can also open a discussion item on our [Documentation Discourse forum](#) [<https://discuss.python.org/c/documentation/26>].

If you're short on time, you can also email documentation bug reports to [docs@python.org](mailto:docs@python.org) (behavioral bugs can be sent to [python-list@python.org](mailto:python-list@python.org)). 'docs@' is a mailing list run by volunteers; your request will be noticed, though it may take a while to be processed.

### See also

## Using the Python issue tracker

Issue reports for Python itself should be submitted via the GitHub issues tracker (<https://github.com/python/cpython/issues>). The GitHub issues tracker offers a web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers' time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the tracker using the search box at the top of the page.

If the problem you're reporting is not already in the list, log in to GitHub. If you don't already have a GitHub account, create a new account using the "Sign up" link. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit an issue. Click on the "New issue" button in the top bar to report a new issue.

The submission form has two fields, "Title" and "Comment".

For the "Title" field, enter a *very* short description of the problem; fewer than ten words is good.

In the "Comment" field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to

include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

Each issue report will be reviewed by a developer who will determine what needs to be done to correct the problem. You will receive an update each time an action is taken on the issue.

### See also

**How to Report Bugs Effectively** [<https://www.chiark.greenend.org.uk/~sgtatham/bugs.html>]

Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

**Bug Writing Guidelines** [<https://bugzilla.mozilla.org/page.cgi?id=bug-writing.html>]

Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.

## Getting started contributing to Python yourself

Beyond just reporting bugs that you find, you are also welcome to submit patches to fix them. You can find more information on how to get started patching Python in the [Python Developer's Guide](https://devguide.python.org/) [<https://devguide.python.org/>]. If you have questions, the [core-mentorship mailing list](https://mail.python.org/mailman3/lists/core-mentorship.python.org/) [<https://mail.python.org/mailman3/lists/core-mentorship.python.org/>] is a friendly place to get answers to any and all questions pertaining to the process of fixing issues in Python.

# History and License

## History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see <https://www.cwi.nl/>) in the Netherlands as a successor of a language called ABC. Guido remains Python's principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see <https://www.cnri.reston.va.us/>) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see <https://www.zope.org/>). In 2001, the Python Software Foundation (PSF, see <https://www.python.org/psf/>) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see <https://opensource.org/> for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

### ~~GPL-compatible?~~

---

~~Python~~ 1991.2

---

~~Python~~ 1995.2

---

~~CWI~~

---

~~BeOpen~~.com

---

~~CNRI~~

---

~~Python~~ 1.6.1

---

~~Python~~ 1.6.1

~~Python~~ 2.0.1

~~Python~~ 2

~~Python~~ 3

~~Python~~ and above

## Note

GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.

## Terms and conditions for accessing or otherwise using Python

Python software and documentation are licensed under the [PSF License Agreement](#).

Starting with Python 3.8.6, examples, recipes, and other code in the documentation are dual licensed under the PSF License Agreement and the [Zero-Clause BSD license](#).

Some software incorporated into Python is under different licenses. The licenses are listed with code falling under that license. See [Licenses and Acknowledgements for Incorporated Software](#) for an incomplete list of these licenses.

## PSF LICENSE AGREEMENT FOR PYTHON 3.11.3

1. This LICENSE AGREEMENT is between the Python Software the Individual or Organization ("Licensee") accessing 3.11.3 software in source or binary form and its asso

2. Subject to the terms and conditions of this License A grants Licensee a nonexclusive, royalty-free, world-w analyze, test, perform and/or display publicly, prepa distribute, and otherwise use Python 3.11.3 alone or version, provided, however, that PSF's License Agree copyright, i.e., "Copyright © 2001–2023 Python Softwa Reserved" are retained in Python 3.11.3 alone or in a prepared by Licensee.
3. In the event Licensee prepares a derivative work that incorporates Python 3.11.3 or any part thereof, and w derivative work available to others as provided herei agrees to include in any such work a brief summary of 3.11.3.
4. PSF is making Python 3.11.3 available to Licensee on PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS C EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAI WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTIC USE OF PYTHON 3.11.3 WILL NOT INFRINGE ANY THIRD PART
5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USER FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 3. THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

8. By copying, installing or otherwise using Python 3.11 to be bound by the terms and conditions of this Licer

# BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

## BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen", 160 Saratoga Avenue, Santa Clara, CA 95051, and the Licensee ("Licensee") accessing and otherwise using this software in source code form and its associated documentation ("the Software").
2. Subject to the terms and conditions of this BeOpen Python License, BeOpen hereby grants Licensee a non-exclusive, royalty-free license to reproduce, analyze, test, perform and/or display publicly, to make works, distribute, and otherwise use the Software alone or in any version, provided, however, that the BeOpen Python License Software, alone or in any derivative version prepared by Licensee, bears the following text in prominent form: "BeOpen Python License Software, Copyright (c) 1998 BeOpen.com. All Rights Reserved." Licensee shall also cause the Software to be distributed with a copy of this license.
3. BeOpen is making the Software available to Licensee on an "AS IS" BASIS. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED, BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE. THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.
4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
5. This License Agreement will automatically terminate upon the use of the Software without its terms and conditions.
6. This License Agreement shall be governed by and interpreted under the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to constitute a partnership, agency, partnership, or joint venture between BeOpen and Licensee. This Agreement does not grant permission to use BeOpen trademarks in a trademark sense to endorse or promote products or services of a third party. As an exception, the "BeOpen Python" logo located at <http://www.pythonlabs.com/logos.html> may be used according to the terms and conditions set forth in the logo's license.

granted on that web page.

7. By copying, installing or otherwise using the software, you are bound by the terms and conditions of this License Agreement.

## **CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1**

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") wishing to use Python 1.6.1 software in source or binary form and/or otherwise using Python 1.6.1 software in source or binary form and/or associated documentation.
2. Subject to the terms and conditions of this License Agreement, CNRI grants Licensee a nonexclusive, royalty-free, world-wide license to copy, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in combination with other provided, however, that CNRI's License Agreement and associated documentation, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives. All Rights Reserved" are retained in Python 1.6.1 alone or in combination with other prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the line number) is made available subject to the terms and conditions of this License Agreement. This Agreement together with Python 1.6.1 software is made available on the internet using the following unique, persistent identifier: 1895.22/1013. This Agreement may also be obtained from CNRI on the internet using the following URL: <http://hdl.handle.net/1895.22/1013>.
3. In the event Licensee prepares a derivative work that incorporates Python 1.6.1 or any part thereof, and makes such work available to others as provided herein, then Licensee must include in any such work a brief summary of the changes made.
4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO, WARRANTIES OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USER FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1 THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.
6. This License Agreement will automatically terminate upon the expiration of its terms and conditions.
7. This License Agreement shall be governed by the federal law of the United States, including without limitation federal law, and, to the extent such U.S. federal law does not apply, the law of the Commonwealth of Virginia, excluding Virginia's conflict of laws provisions. Notwithstanding the foregoing, with regard to derivative works of Python 1.6.1 that incorporate non-separable material that was developed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to such material. With respect to Paragraphs 4, 5, and 7 of this License Agreement, this License Agreement shall be deemed to create no partnership, joint venture, or joint enterprise between CNRI and Licensee, and does not grant permission to use CNRI trademarks or trade names, nor to use the name of CNRI in any sense to endorse or promote products or services of Licensee or any third party.
8. By clicking on the "ACCEPT" button where indicated, or by otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

## **CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2**

Copyright © 1991 - 1995, Stichting Mathematisch Centrum  
Amsterdam, The Netherlands. All rights reserved.

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that this permission notice and this permission notice appear in supporting documentation.

## UUencode and UUdecode functions

The `uu` module contains the following notice:

Copyright 1994 by Lance Ellinghouse  
Cathedral City, California Republic, United States of America  
All Rights Reserved

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies, and that both that copyright notice and this permission notice appear in all supporting documentation, and that the name of Lance Ellinghouse not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission. LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:

- Use `binascii` module to do the actual line-by-line conversion between `ascii` and `binary`. This results in a 1000-fold speedup. The version is still 5 times faster, though.
- Arguments more compliant with Python standard

## XML Remote Procedure Calls

The `xmlrpc.client` module contains the following notice:

The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB  
Copyright (c) 1999-2002 by Fredrik Lundh

By obtaining, using, and/or copying this software and/or associated documentation, you agree that you have read, and will comply with the following terms and conditions:

Permission to use, copy, modify, and distribute this software and its associated documentation for any purpose and without restriction is hereby granted, provided that the above copyright notice appear in all copies, and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Secret Labs AB or the author not be used in advertising or publicity pertaining to distribution of the software without specific prior permission.

SECRET LABS AB AND THE AUTHOR DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. IN NO EVENT SHALL SECRET LABS AB OR THE AUTHOR BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

## **test\_epoll**

The **test\_epoll** module contains the following notice:

Copyright (c) 2001-2006 Twisted Matrix Laboratories.

Permission is hereby granted, free of charge, to any person obtaining a copy of this software and associated documentation files (the "Software"), to deal in the Software without restriction, including without limitation the rights to use, copy, modify, merge, publish, distribute, sublicense, and/or sell copies of the Software, and to permit persons to whom the Software is furnished to do so, on the following conditions:

# Distributing Python Modules (Legacy version)

## Authors

Greg Ward, Anthony Baxter

## Email

[distutils-sig@python.org](mailto:distutils-sig@python.org)

## See also

### Distributing Python Modules

The up to date module distribution documentations

## Note

The entire `distutils` package has been deprecated and will be removed in Python 3.12. This documentation is retained as a reference only, and will be removed with the package. See the [What's New](#) entry for more information.

## Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

## Note

This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure

alternatives. Refer to the [quick recommendations section](https://packaging.python.org/guides/tool-recommendations/) [https://packaging.python.org/guides/tool-recommendations/] in the Python Packaging User Guide for more information.

This document describes the Python Distribution Utilities (“Distutils”) from the module developer’s point of view, describing the underlying capabilities that `setuptools` builds on to allow Python developers to make Python modules and extensions readily available to a wider audience.

- 1. An Introduction to Distutils
  - 1.1. Concepts & Terminology
  - 1.2. A Simple Example
  - 1.3. General Python terminology
  - 1.4. Distutils-specific terminology
- 2. Writing the Setup Script
  - 2.1. Listing whole packages
  - 2.2. Listing individual modules
  - 2.3. Describing extension modules
  - 2.4. Relationships between Distributions and Packages
  - 2.5. Installing Scripts

the standard getopt module

- 9.17. **distutils.filelist** — The FileList class
- 9.18. **distutils.log** — Simple PEP 282-style logging
- 9.19. **distutils.spawn** — Spawn a sub-process
- 9.20. **distutils.sysconfig** — System configuration information
- 9.21. **distutils.text\_file** — The TextFile class
- 9.22. **distutils.version** — Version number classes
- 9.23. **distutils.cmd** — Abstract base class for Distutils commands
- 9.24. Creating a new Distutils command
- 9.25. **distutils.command** — Individual Distutils commands
- 9.26. **distutils.command.bdist** — Build a binary installer
- 9.27. **distutils.command.bdist\_packager** — Abstract base class for packagers
- 9.28. **distutils.command.bdist\_dumb** — Build a “dumb” installer
- 9.29. **distutils.command.bdist\_rpm** — Build a binary distribution as a Redhat RPM and SRPM
- 9.30. **distutils.command.sdist** — Build a source distribution
- 9.31. **distutils.command.build** — Build all files of a package
- 9.32. **distutils.command.build\_clib** — Build any C libraries in a package
- 9.33. **distutils.command.build\_ext** — Build any extensions in a package
- 9.34. **distutils.command.build\_py** — Build the .py/.pyc files of a package
- 9.35. **distutils.command.build\_scripts** — Build the scripts of a package
- 9.36. **distutils.command.clean** — Clean a package build area
- 9.37. **distutils.command.config** — Perform package configuration
- 9.38. **distutils.command.install** — Install a

package

- 9.39. **`distutils.command.install_data`** — Install data files from a package
- 9.40. **`distutils.command.install_headers`** — Install C/C++ header files from a package
- 9.41. **`distutils.command.install_lib`** — Install library files from a package
- 9.42. **`distutils.command.install_scripts`** — Install script files from a package
- 9.43. **`distutils.command.register`** — Register a module with the Python Package Index
- 9.44. **`distutils.command.check`** — Check the meta-data of a package

# 1. An Introduction to Distutils

## Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the [Installing Python Modules \(Legacy version\)](#) chapter.

## 1.1. Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (`setup.py` by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it's not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called *packagers*, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus,

users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.

## 1.2. A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called `foo`, contained in a file `foo.py`, then your setup script can be as simple as this:

```
from distutils.core import setup
setup(name='foo',
 version='1.0',
 py_modules=['foo'],
)
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section [Writing the Setup Script](#) for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run this command from a terminal:

```
python setup.py sdist
```

For Windows, open a command prompt window (*Start ▶ Accessories*) and change the command to:

```
setup.py sdist
```

**sdist** will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your `foo` module, all they have to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils *commands* they use: the **sdist** command is almost exclusively for module developers, while **install** is more often for installers (although most developers will want to install their own code occasionally).

Other useful built distribution formats are RPM, implemented by the **bdist\_rpm** command, Solaris **pkgtool** (**bdist\_pkgtool**), and HP-UX **swinstall** (**bdist\_sdux**). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The **bdist\_rpm** command uses the **rpm** executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time

by running

```
python setup.py bdist --help-formats
```

## 1.3. General Python terminology

If you're reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

### module

the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

### pure Python module

a module written in Python and contained in a single `.py` file (and possibly associated `.pyc` files). Sometimes referred to as a “pure module.”

### extension module

a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (`.so`) file for Python extensions on Unix, a DLL (given the `.pyd` extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

### package

a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file `__init__.py`.

### root package

the root of the hierarchy of packages. (This isn't really a package, since it doesn't have an `__init__.py` file. But we

have to call it something.) The vast majority of the standard library is in the root package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in `sys.path` contributes modules to the root package.

## 1.4. Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution

a collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are NumPy, SciPy, Pillow, or mxBase. (This would be called a *package*, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution

a module distribution that contains only pure Python modules and packages. Sometimes referred to as a “pure distribution.”

non-pure module distribution

a module distribution that contains at least one extension module. Sometimes referred to as a “non-pure distribution.”

distribution root

the top-level directory of your source tree (or source distribution); the directory where `setup.py` exists. Generally `setup.py` will be run from this directory.

## 2. Writing the Setup Script

### Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section [A Simple Example](#) above, the setup script consists mainly of a call to `setup()`, and most information supplied to the Distutils by the module developer is supplied as keyword arguments to `setup()`.

Here's a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils' own setup script, shown here, is used to install the package into Python 1.5.2.)

```
#!/usr/bin/env python
```

```
from distutils.core import setup
```

```
setup(name='Distutils',
 version='1.0',
 description='Python Distribution Utilities',
 author='Greg Ward',
 author_email='gward@python.net',
```

```
url='https://www.python.org/sigs/distutils-sig/',
packages=['distutils', 'distutils.command'],
)
```

There are only two differences between this and the trivial one-file distribution presented in section [A Simple Example](#): more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section [Additional meta-data](#).

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as [glob.glob\(\)](#) or [os.listdir\(\)](#) to specify files, you should be careful to write portable code instead of hardcoding path separators:

```
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```

## 2.1. Listing whole packages

The `packages` option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the `packages` list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package [distutils](#) is found in the directory `distutils` relative to the distribution root. Thus, when

you say `packages = ['foo']` in your setup script, you are promising that the Distutils will find a file `foo/__init__.py` (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyway.

If you use a different convention to lay out your source directory, that's no problem: you just have to supply the `package_dir` option to tell the Distutils about your convention. For example, say you keep all Python source under `lib`, so that modules in the “root package” (i.e., not in any package at all) are in `lib`, modules in the **foo** package are in `lib/foo`, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say `packages = ['foo']`, you are promising that the file `lib/foo/__init__.py` exists.

Another possible convention is to put the **foo** package right in `lib`, the **foo.bar** package in `lib/bar`, etc. This would be written in the setup script as

```
package_dir = {'foo': 'lib'}
```

A `package: dir` entry in the `package_dir` dictionary implicitly applies to all packages below *package*, so the **foo.bar** case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although `package_dir` applies recursively, you must explicitly list all packages in `packages`: the Distutils will *not* recursively scan your source tree looking for any directory with an `__init__.py` file.)

## 2.2. Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the “root package” (i.e., no package at all). This simplest case was shown in section [A Simple Example](#); here is a slightly more involved example:

```
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the “root” package, the other in the **pkg** package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.

## 2.3. Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it’s not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to `setup()`, the `ext_modules` option. `ext_modules` is just a list of **Extension** instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called **foo** and implemented by `foo.c`. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```
Extension('foo', ['foo.c'])
```

The **Extension** class can be imported from `distutils.core` along with `setup()`. Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```
from distutils.core import setup, Extension
setup(name='foo',
 version='1.0',
 ext_modules=[Extension('foo', ['foo.c'])],
)
```

The **Extension** class (actually, the underlying extension-building machinery implemented by the **build\_ext** command) supports a great deal of flexibility in describing Python extensions, which is explained in the following sections.

### 2.3.1. Extension names and packages

The first argument to the **Extension** constructor is always the name of the extension, including any package names. For example,

```
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the **pkg** package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python's namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to **setup()**. For example,

```
setup(...,
 ext_package='pkg',
 ext_modules=[Extension('foo', ['foo.c']),
 Extension('subpkg.bar', ['bar.c'])],
)
```

will compile `foo.c` to the extension **pkg.foo**, and `bar.c` to **pkg.subpkg.bar**.

### 2.3.2. Extension source files

The second argument to the **Extension** constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish C++ source files: `.cc` and `.cpp` seem to be recognized by both Unix and Windows compilers.)

However, you can also include SWIG interface (`.i`) files in the list; the **build\_ext** command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

This warning notwithstanding, options to SWIG can be currently passed like this:

```
setup(...,
 ext_modules=[Extension('_foo', ['foo.i'],
 swig_opts=['-modern', '-I..'],
 py_modules=['foo'],
)
]
)
```

Or on the commandline like this:

```
> python setup.py build_ext --swig-opts="-modern -I../include"
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (`.mc`) files and resource definition (`.rc`) files for Visual C++. These will be compiled to binary resource (`.res`) files and linked into the executable.

### 2.3.3. Preprocessor options

Three optional arguments to **Extension** will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the

`include_dirs` option:

```
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```
Extension('foo', ['foo.c'], include_dirs=['/usr/include/'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it's probably better to write C code like

```
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils **`install_headers`** command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory—`/usr/local/include/python1.5` in this case—is always included in the search path when building Python extensions, the best approach is to write C code like

```
#include <Numerical/arrayobject.h>
```

If you must put the Numerical include directory right into your header search path, though, you can find that directory using the Distutils **`distutils.sysconfig`** module:

```
from distutils.sysconfig import get_python_inc
incdir = os.path.join(get_python_inc(plat_specific=1), 'Numerical')
setup(...,
 Extension(..., include_dirs=[incdir]),
)
```

Even though this is quite portable—it will work on any Python installation, regardless of platform—it's probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of (name, value) tuples, where name is the name of the macro to define (a string) and value is its value: either a string or `None`. (Defining a macro `FOO` to `None` is the equivalent of a bare `#define FOO` in your C source: with most compilers, this sets `FOO` to the string `1`.) `undef_macros` is just a list of macros to undefine.

For example:

```
Extension(...,
 define_macros=[('NDEBUG', '1'),
 ('HAVE_STRFTIME', None)],
 undef_macros=['HAVE_FOO', 'HAVE_BAR'])
```

is the equivalent of having this at the top of every C source file:

```
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

### 2.3.4. Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and `runtime_library_dirs` is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```
Extension(...,
 libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in `library_dirs`:

```
Extension(...,
 library_dirs=['/usr/X11R6/lib'],
 libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

### 2.3.5. Other options

There are still some other options which can be used to handle special cases.

The `optional` option is a boolean; if it is true, a build failure in the extension will not abort the build process, but instead simply not install the failing extension.

The `extra_objects` option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

`extra_compile_args` and `extra_link_args` can be used to specify additional command line options for the respective compiler and linker command lines.

`export_symbols` is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add `initmodule` to the list of exported symbols.

The `depends` option is a list of files that the extension depends on (for example header files). The build command will call the compiler on the sources to rebuild extension if any on this files has been modified since the previous build.

## 2.4. Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.

2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the *requires* keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include 'mymodule' and 'xml.parsers.expat'.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
< > ==
<= >= !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.

Let's look at a bunch of examples:

### Replacem~~ent~~ Expression

---

Only version 1.0 is compatible

---

Any version after 1.0 and before 2.0 is compatible, except 1.5.1

---

Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the *provides* keyword argument to `setup()`. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

### **Provides Expression**

---

**Provide** mypkg, using the distribution version

---

**Provide** (mypkg version 1.1, regardless of the distribution version

---

A package can declare that it obsoletes other packages using the *obsoletes* keyword argument. The value for this is similar to that of the *requires* keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all versions of the named module or package are understood to be obsoleted.

## **2.5. Installing Scripts**

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don't require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word "python", the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The **--executable** (or **-e**) option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```
setup(...,
 scripts=['scripts/xmlproc_parse', 'scripts/xmlproc
)
```

*Changed in version 3.1:* All the scripts will also be added to the MANIFEST file if no template is provided. See [Specifying the files to distribute](#).

## 2.6. Installing Package Data

Often, additional files need to be installed into a package. These files are often data that's closely related to the package's implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```
setup.py
src/
 mypkg/
 __init__.py
 module.py
 data/
 tables.dat
 spoons.dat
 forks.dat
```

The corresponding call to `setup()` might be:

```

setup(...,
 packages=['mypkg'],
 package_dir={'mypkg': 'src/mypkg'},
 package_data={'mypkg': ['data/*.dat']},
)

```

*Changed in version 3.1:* All the files that match `package_data` will be added to the MANIFEST file if no template is provided. See [Specifying the files to distribute](#).

## 2.7. Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn't fit in the previous categories.

`data_files` specifies a sequence of (*directory*, *files*) pairs in the following way:

```

setup(...,
 data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif'],
 ('config', ['cfg/data.cfg'])),
]
)

```

Each (*directory*, *files*) pair in the sequence specifies the installation directory and the files to install there.

Each file name in *files* is interpreted relative to the `setup.py` script at the top of the package source distribution. Note that you can specify the directory where the data files will be installed, but you cannot rename the data files themselves.

The *directory* should be a relative path. It is interpreted relative to the installation prefix (Python's `sys.prefix` for system installations; `site.USER_BASE` for user installations). Distutils allows *directory* to be an absolute installation path, but this is discouraged since it is incompatible with the wheel packaging format. No directory information from *files* is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the **install** command will print a warning in this case. To install data files directly in the target directory, an empty string should be given as the directory.

*Changed in version 3.1:* All the files that match `data_files` will be added to the `MANIFEST` file if no template is provided. See [Specifying the files to distribute](#).

## 2.8. Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

Meta-data
<code>name</code> string package name
<code>version</code> string version of this release
<code>author</code> string author's name
<code>author_email</code> string email address of the package author
<code>maintainer</code> string maintainer's name
<code>maintainer_email</code> string email address of the package maintainer
<code>url</code> string the page for the package
<code>short_description</code> string short, summary description of the package
<code>long_description</code> string long description of the package
<code>download_url</code> string URL where the package may be downloaded
<code>classifiers</code> list of strings
<code>platforms</code> list of strings
<code>keywords</code> list of keywords
<code>license</code> string license for the package

Notes:

1. These fields are required.
2. It is recommended that versions take the form *major.minor[.patch[.sub]]*.
3. Either the author or the maintainer must be identified. If maintainer is provided, distutils lists it as the author in `PKG-INFO`.
4. The `long_description` field is used by PyPI when you

publish a package, to build its project page.

5. The `license` field is a text indicating the license covering the package where the license is not a selection from the “License” Trove classifiers. See the `Classifier` field. Notice that there’s a `licence` distribution option which is deprecated but still acts as an alias for `license`.
6. This field must be a list.
7. The valid classifiers are listed on [PyPI](https://pypi.org/classifiers) [https://pypi.org/classifiers].
8. To preserve backward compatibility, this field also accepts a string. If you pass a comma-separated string `'foo, bar'`, it will be converted to `['foo', 'bar']`, Otherwise, it will be converted to a list of one string.

‘short string’

A single line of text, not more than 200 characters.

‘long string’

Multiple lines of plain text in reStructuredText format (see <http://docutils.sourceforge.net/>).

‘list of strings’

See below.

Encoding the version information is an art in itself. Python packages generally adhere to the version format *major.minor[.patch][sub]*. The major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are “a1,a2,...,aN” (for alpha releases, where functionality and API may change), “b1,b2,...,bN” (for beta releases, which only fix bugs) and “pr1,pr2,...,prN” (for final pre-release release testing). Some examples:

0.1.0

the first, experimental release of a package

1.0.1a2

the second alpha release of the first patch version of 1.0

classifiers must be specified in a list:

```
setup(...,
 classifiers=[
 'Development Status :: 4 - Beta',
 'Environment :: Console',
 'Environment :: Web Environment',
 'Intended Audience :: End Users/Desktop',
 'Intended Audience :: Developers',
 'Intended Audience :: System Administrators',
 'License :: OSI Approved :: Python Software Foundation License',
 'Operating System :: MacOS :: MacOS X',
 'Operating System :: Microsoft :: Windows',
 'Operating System :: POSIX',
 'Programming Language :: Python',
 'Topic :: Communications :: Email',
 'Topic :: Office/Business',
 'Topic :: Software Development :: Bug Tracking',
],
)
```

*Changed in version 3.7:* **setup** now warns when `classifiers`, `keywords` or `platforms` fields are not specified as a list or a string.

## 2.9. Debugging the setup script

Sometimes things go wrong, and the setup script doesn't do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don't know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don't read all the way down to the bottom and see that it's a permission problem.

On the other hand, this doesn't help the developer to find the cause of the failure. For this purpose, the **DISTUTILS\_DEBUG** environment variable can be set to anything except an empty string, and distutils will now print detailed information about what it is doing, dump the full traceback when an exception occurs, and print the whole command line when an external program (like a C compiler) fails.

# 3. Writing the Setup Configuration File

## Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

Often, it's not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user's system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, `setup.cfg`, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers 1—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, `setup.cfg` (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in `setup.py` by editing `setup.cfg`
- you can provide non-standard defaults for options that are not easily set in `setup.py`
- installers can override anything in `setup.cfg` using the command-line options to `setup.py`

The basic syntax of the configuration file is simple:

```
[command]
option=value
...
```

where *command* is one of the Distutils commands (e.g. **build\_py**, **install**), and *option* is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a '#' character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal **--help** option, e.g.

```
$ python setup.py --help build_ext
[...]
Options for 'build_ext' command:
--build-lib (-b) directory for compiled extension
--build-temp (-t) directory for temporary files (bu
--inplace (-i) ignore build-lib and put compiled
 source directory alongside your p
--include-dirs (-I) list of directories to search for
--define (-D) C preprocessor macros to define
--undef (-U) C preprocessor macros to undefine
--swig-opts list of SWIG command line options
[...]
```

Note that an option spelled **--foo-bar** on the command-line is spelled `foo_bar` in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension **pkg.ext**, and you want the compiled extension file (`ext.so` on Unix, say) to be put in the same source directory as your pure Python modules **pkg.mod1** and **pkg.mod2**. You can always use the **--inplace** option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the **build\_ext** command explicitly, and remember to provide **--inplace**. An easier way is to “set and forget” this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify **build\_ext**. If you include `setup.cfg` in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don’t change from run to run; for example, **bdist\_rpm** needs to know everything required to generate a “spec” file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to **bdist\_rpm**, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils’ own `setup.cfg`:

```
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
 README.txt
 USAGE.txt
 doc/
 examples/
```

Note that the `doc_files` option is simply a whitespace-separated

string split across multiple lines for readability.

#### **Syntax of config files in “Installing Python Modules”**

More information on the configuration files is available in the manual for system administrators.

### Footnotes

1

This ideal probably won't be achieved until auto-configuration is fully supported by the Distutils.

## 4. Creating a Source Distribution

### Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

As shown in section [A Simple Example](#), you use the **`sdist`** command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven't specified any **`sdist`** options in the setup script or config file), **`sdist`** creates the archive of the default format for the current platform. The default format is a gzip'ed tar file (`.tar.gz`) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the **`--formats`** option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

### Description

(zip)	file (.zip)
(gztar)	gzip'ed tar file (.tar.gz)
(bz2tar)	bzip2'ed tar file (.tar.bz2)
(xztar)	xzip'ed tar file (.tar.xz)
(jartar)	compressed tar file (.tar.Z)
(tar)	file (.tar)

*Changed in version 3.5:* Added support for the `xz` format.

Notes:

1. default on Windows
2. default on Unix
3. requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)
4. requires the **compress** program. Notice that this format is now pending for deprecation and will be removed in the future versions of Python.
5. deprecated by [PEP 527](https://peps.python.org/pep-0527/) [https://peps.python.org/pep-0527/]; [PyPI](https://pypi.org) [https://pypi.org] only accepts `.zip` and `.tar.gz` files.

When using any `tar` format (`gztar`, `bztar`, `xztar`, `ztar` or `tar`), under Unix you can specify the `owner` and `group` names that will be set for each member of the archive.

For example, if you want all files of the archive to be owned by `root`:

```
python setup.py sdist --owner=root --group=root
```

## 4.1. Specifying the files to distribute

If you don't supply an explicit list of files (or instructions on how to generate one), the `sdist` command puts a minimal default set into the source distribution:

- all Python source files implied by the `py_modules` and `packages` options
- all C source files mentioned in the `ext_modules` or `libraries` options
- scripts identified by the `scripts` option See [Installing Scripts](#).
- anything that looks like a test script: `test/test*.py` (currently, the Distutils don't do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)

- Any of the standard README files (README, README.txt, or README.rst), setup.py (or whatever you called your setup script), and setup.cfg.
- all files that matches the `package_data` metadata. See [Installing Package Data](#).
- all files that matches the `data_files` metadata. See [Installing Additional Files](#).

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a *manifest template*, called `MANIFEST.in` by default. The manifest template is just a list of instructions for how to generate your manifest file, `MANIFEST`, which is the exact list of files to include in your source distribution. The **sdist** command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one filename per line, regular files (or symlinks to them) only. If you do supply your own `MANIFEST`, you must specify everything: the default set of files described above does not apply in this case.

*Changed in version 3.1:* An existing generated `MANIFEST` will be regenerated without **sdist** comparing its modification time to the one of `MANIFEST.in` or `setup.py`.

*Changed in version 3.1.3:* `MANIFEST` files start with a comment indicating they are generated. Files without this comment are not overwritten or removed.

*Changed in version 3.2.2:* **sdist** will read a `MANIFEST` file if no `MANIFEST.in` exists, like it used to do.

*Changed in version 3.7:* `README.rst` is now included in the list of distutils standard READMEs.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample?/build
```

The meanings should be fairly clear: include all files in the distribution root matching `*.txt`, all files anywhere under the `examples` directory matching `*.txt` or `*.py`, and exclude all directories matching `examples/sample?/build`. All of this is done *after* the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the `--no-defaults` option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section [Creating a source distribution: the `sdist` command](#).

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils “build” tree (default `build/`)
- all files in directories named `RCS`, `CVS`, `.svn`, `.hg`, `.git`, `.bzz` or `_darcs`

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the `--no-defaults` option, and you can disable the standard exclude set with `--no-prune`.

Following the Distutils’ own manifest template, let’s trace how the `sdist` command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the `distutils` and `distutils/command` subdirectories (because packages corresponding to those two directories were mentioned in the `packages` option in the setup script—see section [Writing the](#)

### Setup Script)

2. include `README.txt`, `setup.py`, and `setup.cfg` (standard files)
3. include `test/test*.py` (standard files)
4. include `*.txt` in the distribution root (this will find `README.txt` a second time, but such redundancies are weeded out later)
5. include anything matching `*.txt` or `*.py` in the sub-tree under `examples`,
6. exclude all files in the sub-trees starting at directories matching `examples/sample?/build`—this may exclude files included by the previous two steps, so it's important that the `prune` command in the manifest template comes after the `recursive-include` command
7. exclude the entire `build` tree, and any `RCS`, `CVS`, `.svn`, `.hg`, `.git`, `.bzip` and `_darcs` directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.

## 4.2. Manifest-related options

The normal course of operations for the `sdist` command is as follows:

- if the manifest file (`MANIFEST` by default) exists and the first line does not have a comment indicating it is generated from `MANIFEST.in`, then it is used as is, unaltered
- if the manifest file doesn't exist or has been previously automatically generated, read `MANIFEST.in` and create the manifest
- if neither `MANIFEST` nor `MANIFEST.in` exist, create a manifest with just the default file set
- use the list of files now in `MANIFEST` (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use

the **--no-defaults** and **--no-prune** to disable the standard “include” and “exclude” sets.

Second, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

**-o** is a shortcut for **--manifest-only**.

## 5. Creating Built Distributions

### Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called *packagers* springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be their own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager

uses the setup script and the **bdist** command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:

```
python setup.py bdist
```

then the Distutils builds my module distribution (the Distutils itself in this case), does a “fake” installation (also in the `build` directory), and creates the default type of built distribution for my platform. The default format for built distributions is a “dumb” tar file on Unix, and a simple executable installer on Windows. (That tar file is considered “dumb” because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates `Distutils-1.0.plat.tar.gz`; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run `python setup.py install`. (The “right place” is either the root of the filesystem or Python’s `prefix` directory, depending on the options given to the **bdist\_dumb** command; the default is to make dumb distributions relative to `prefix`.)

Obviously, for pure Python distributions, this isn’t any simpler than just running `python setup.py install`—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating “smart” built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn’t include any extensions.

The **bdist** command has a `--formats` option, similar to the **sdist** command, which you can use to select the types of built distribution to generate: for example,

```
python setup.py bdist --format=zip
```

would, when run on a Unix system, create

`Distutils-1.0.plat.zip`—again, this archive would be unpacked from the root directory to install the Distutils.

The available formats for built distributions are:

### Description

---

~~gzipped~~ tar file (`.tar.gz`)

~~bzipped~~ tar file (`.tar.bz2`)

~~xzipped~~ tar file (`.tar.xz`)

~~compressed~~ tar file (`.tar.Z`)

tar file (`.tar`)

~~zip file~~ (`.zip`)

~~RPM~~

Solaris `pkgtool`

HP-UX `swinstall`

Microsoft Installer.

---

*Changed in version 3.5:* Added support for the `xztar` format.

Notes:

1. default on Unix
2. default on Windows
3. requires external **compress** utility.
4. requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)
5. requires external **rpm** utility, version 3.0.4 or better (use `rpm --version` to find out which version you have)

You don't have to use the **bdist** command with the `--formats` option; you can also use the command that directly implements the format you're interested in. Some of these **bdist** “sub-commands” actually generate several similar formats; for instance, the **bdist\_dumb** command generates all the “dumb” archive formats (`tar`, `gztar`, `bztar`, `xztar`, `ztar`, and `zip`), and **bdist\_rpm** generates both binary and source RPMs. The **bdist** sub-commands, and the formats generated by each, are:

### Command

---

~~bdist\_dumb~~ `gztar`, `xztar`, `ztar`, `zip`

~~bdist\_rpm~~

---

The following sections give details on the individual **bdist\_\*** commands.

## 5.1. Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the **bdist\_rpm** command:

```
python setup.py bdist_rpm
```

or the **bdist** command with the **--format** option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple **bdist\_\*** commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.com>"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the **bdist\_rpm** command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in any Distutils configuration files. Various options and sections in the `.spec` file are derived from options in the setup script as follows:

RPM file	setup script option	section
----------	---------------------	---------

Name		
------	--	--

Summary (in preamble)		
-----------------------	--	--

Version
Vendor and author_email, or — & maintainer and maintainer_email
Copyright
Url
%description (section)

Additionally, there are many options in `.spec` files that don't have corresponding options in the setup script. Most of these are handled through options to the **bdist\_rpm** command as follows:

Red Hat, or any other option or section
Release
Group "Development/Libraries"
(Vendor)
Package
Provides
Requires
Conflicts
Obsoletes
Distribution_name
BuildRequires
(name)

Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it's usually best to put them in the setup configuration file, `setup.cfg`—see section [Writing the Setup Configuration File](#). If you distribute or package many Python module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (`~/.pydistutils.cfg`). If you want to temporarily disable this file, you can pass the **--no-user-cfg** option to `setup.py`.

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a `.spec` file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the `.spec` file)
2. create the source RPM
3. create the “binary” RPM (which may or may not contain

binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the **--spec-only** option to make **bdist\_rpm** just create the `.spec` file and exit; in this case, the `.spec` file will be written to the “distribution directory”—normally `dist/`, but customizable with the **--dist-dir** option. (Normally, the `.spec` file winds up deep in the “build tree,” in a temporary directory created by **bdist\_rpm**.)

## 5.2. Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the **--plat-name** option to the build command. Valid values are currently ‘win32’, and ‘win-amd64’. For example, on a 32bit version of Windows, you could execute:

```
python setup.py build --plat-name=win-amd64
```

to build a 64bit version of your extension.

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targeting - it is not possible from a binary installation of Python (as the `.lib` etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the `PCbuild/PCbuild.sln` solution in the Python source tree and build the “x64” configuration of the ‘pythoncore’ project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel-> [Add/Remove] Programs is a convenient way to check or modify your existing install.)

### 5.2.1. The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified with the **--install-script** option. The basename of the script must be specified, and the script filename must also be listed in the `scripts` argument to the `setup` function.

This script will be run at installation time on the target system after all the files have been copied, with `argv[1]` set to **-install**, and again at uninstallation time before the files are removed with `argv[1]` set to **-remove**.

The installation script runs embedded in the windows installer, every output (`sys.stdout`, `sys.stderr`) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

`directory_created(path)`

`file_created(path)`

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register *path* with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

`get_special_folder_path(csidl_string)`

This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. *csidl\_string* must be one of the following strings:

"CSIDL\_APPDATA"

"CSIDL\_COMMON\_STARTMENU"

"CSIDL\_STARTMENU"

"CSIDL\_COMMON\_DESKTOPDIRECTORY"

"CSIDL\_DESKTOPDIRECTORY"

"CSIDL\_COMMON\_STARTUP"

"CSIDL\_STARTUP"

"CSIDL\_COMMON\_PROGRAMS"

"CSIDL\_PROGRAMS"

"CSIDL\_FONTS"

If the folder cannot be retrieved, **OSError** is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the **SHGetSpecialFolderPath()** function.

`create_shortcut(target, description, filename[, arguments[, workdir[, iconpath[, iconindex]]]])`

This function creates a shortcut. *target* is the path to the program to be started by the shortcut. *description* is the description of the shortcut. *filename* is the title of the shortcut that the user will see. *arguments* specifies the command line arguments, if any. *workdir* is the working directory for the program. *iconpath* is the file containing the icon for the shortcut, and *iconindex* is the index of the icon in the file *iconpath*. Again, for details consult the Microsoft documentation for the **IShellLink** interface.

## 6. Distutils Examples

### Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

### See also

**Distutils Cookbook** [<https://wiki.python.org/moin/Distutils/Cookbook>]

Collection of recipes showing how to achieve more control over distutils.

### 6.1. Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the `py_modules` option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, `foo.py` in this example:

```
<root>/
 setup.py
 foo.py
```

(In all diagrams in this section, `<root>` will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```
from distutils.core import setup
setup(name='foo',
 version='1.0',
 py_modules=['foo'],
)
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules `foo` and `bar`, your setup might look like this:

```
<root>/
 setup.py
 foo.py
 bar.py
```

and the setup script might be

```
from distutils.core import setup
setup(name='foobar',
 version='1.0',
 py_modules=['foo', 'bar'],
)
```

You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.

## 6.2. Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an `__init__.py` file).

The setup script from the last example could also be written as

```
from distutils.core import setup
setup(name='foobar',
 version='1.0',
 packages=[''],
)
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
 setup.py
 src/ foo.py
 bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```
from distutils.core import setup
setup(name='foobar',
 version='1.0',
 package_dir={'': 'src'},
 packages=[''],
)
```

More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the **foo** and **bar** modules belong in package **foobar**, one way to layout your source tree is

```

<root>/
 setup.py
 foobar/
 __init__.py
 foo.py
 bar.py

```

This is in fact the default layout expected by the Distutils, and the one that requires the least work to describe in your setup script:

```

from distutils.core import setup
setup(name='foobar',
 version='1.0',
 packages=['foobar'],
)

```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the **foobar** package:

```

<root>/
 setup.py
 src/
 __init__.py
 foo.py
 bar.py

```

an appropriate setup script would be

```

from distutils.core import setup
setup(name='foobar',
 version='1.0',
 package_dir={'foobar': 'src'},
 packages=['foobar'],
)

```

Or, you might put modules from your main package right in the distribution root:

```
<root>/
 setup.py
 __init__.py
 foo.py
 bar.py
```

in which case your setup script would be

```
from distutils.core import setup
setup(name='foobar',
 version='1.0',
 package_dir={'foobar': ''},
 packages=['foobar'],
)
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does *not* scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:

```
<root>/
 setup.py
 foobar/
 __init__.py
 foo.py
 bar.py
 subfoo/
 __init__.py
 blah.py
```

then the corresponding setup script would be

```
from distutils.core import setup
setup(name='foobar',
 version='1.0',
 packages=['foobar', 'foobar.subfoo'],
```

)

## 6.3. Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```
<root>/
 setup.py
 foo.c
```

If the **foo** extension belongs in the root package, the setup script for this could be

```
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
 version='1.0',
 ext_modules=[Extension('foo', ['foo.c'])],
)
```

If the extension actually belongs in a package, say **foopkg**, then

With exactly the same source tree layout, this extension can be put in the **foopkg** package simply by changing the name of the extension:

```
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
 version='1.0',
 ext_modules=[Extension('foopkg.foo', ['foo.c'])],
)
```

## 6.4. Checking a package

The `check` command allows you to verify if your package meta-

data meet the minimum requirements to build a distribution.

To run it, just call it using your `setup.py` script. If something is missing, `check` will display a warning.

Let's take an example with a simple script:

```
from distutils.core import setup

setup(name='foobar')
```

Running the `check` command will display some warnings:

```
$ python setup.py check
running check
warning: check: missing required meta-data: version, url
warning: check: missing meta-data: either (author and au
 (maintainer and maintainer_email) should be sup
```

If you use the `reStructuredText` syntax in the `long_description` field and [docutils](http://docutils.sourceforge.net) [http://docutils.sourceforge.net] is installed you can check if the syntax is fine with the `check` command, using the `restructuredtext` option.

For example, if the `setup.py` script is changed like this:

```
from distutils.core import setup

desc = """\
My description
=====

This is the description of the ``foobar`` package.
"""

setup(name='foobar', version='1', author='tarek',
 author_email='tarek@ziade.org',
 url='http://example.com', long_description=desc)
```

Where the long description is broken, `check` will be able to detect it by using the `docutils` parser:

```
$ python setup.py check --restructuredtext
running check
warning: check: Title underline too short. (line 2)
warning: check: Could not finish the parsing.
```

## 6.5. Reading the metadata

The `distutils.core.setup()` function provides a command-line interface that allows you to query the metadata fields of a project through the `setup.py` script of a given project:

```
$ python setup.py --name
distribute
```

This call reads the `name` metadata by running the `distutils.core.setup()` function. Although, when a source or binary distribution is created with Distutils, the metadata fields are written in a static file called `PKG-INFO`. When a Distutils-based project is installed in Python, the `PKG-INFO` file is copied alongside the modules and packages of the distribution under `NAME-VERSION-pyX.X.egg-info`, where `NAME` is the name of the project, `VERSION` its version as defined in the Metadata, and `pyX.X` the major and minor version of Python like `2.7` or `3.2`.

You can read back this static file, by using the `distutils.dist.DistributionMetadata` class and its `read_pkg_file()` method:

```
>>> from distutils.dist import DistributionMetadata
>>> metadata = DistributionMetadata()
>>> metadata.read_pkg_file(open('distribute-0.6.8-py2.7.
>>> metadata.name
'distribute'
>>> metadata.version
'0.6.8'
>>> metadata.description
'Easily download, build, install, upgrade, and uninstall
```

Notice that the class can also be instantiated with a metadata file path to loads its values:

```
>>> pkg_info_path = 'distribute-0.6.8-py2.7.egg-info'
>>> DistributionMetadata(pkg_info_path).name
'distribute'
```

# 7. Extending Distutils

## Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within `setup.py` scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to `.py` files as a convenience.

Most distutils command implementations are subclasses of the `distutils.cmd.Command` class. New commands may directly inherit from `Command`, while replacements often derive from `Command` indirectly, directly subclassing the command they are replacing. Commands are required to derive from `Command`.

## 7.1. Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your `setup.py` script, and cause the `distutils.core.setup()` function use them:

```
from distutils.command.build_py import build_py as _build
from distutils.core import setup

class build_py(_build_py):
 """Specialized Python source builder."""

 # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
 ...)
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing `setup.py` scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything `distutils` commands can be used for. A new configuration option, `command_packages` (command-line option **`--command-packages`**), can be used to specify additional packages to be searched for modules implementing commands. Like all `distutils` options, this can be specified on the command line or in a configuration file. This option can only be set in the `[global]` section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not

specified, the search is only performed in the `distutils.command` package. When `setup.py` is run with the option `--command-packages distcmds,buildcmds`, however, the packages `distutils.command`, `distcmds`, and `buildcmds` will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command `bdist_openpkg` could be implemented by the class `distcmds.bdist_openpkg.bdist_openpkg` or `buildcmds.bdist_openpkg.bdist_openpkg`.

## 7.2. Adding new distribution types

Commands that create distributions (files in the `dist/` directory) need to add `(command, filename)` pairs to `self.distribution.dist_files` so that **upload** can upload it to PyPI. The *filename* in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.

## 8. Command Reference

### Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

### 8.1. Installing modules: the `install` command family

The `install` command ensures that the build commands have been run and then runs the subcommands `install_lib`, `install_data` and `install_scripts`.

#### 8.1.1. `install_data`

This command installs all data files provided with the distribution.

#### 8.1.2. `install_scripts`

This command installs all (Python) scripts in the distribution.

### 8.2. Creating a source distribution: the `sdist` command

The manifest template commands are:

Description
<code>include_package_data</code>
<code>exclude_package_data</code>
<code>recursive-include dir pattern</code>

<b>recursive_exclude</b> <i>dir</i> <i>pat1</i> <i>pat2</i>	any of the listed patterns
<b>global_include</b> <i>pat1</i> <i>pat2</i>	in the source tree matching — & any of the listed patterns
<b>global_exclude</b> <i>pat1</i> <i>pat2</i>	in the source tree matching — & any of the listed patterns
<b>prunedir</b>	all files under <i>dir</i>
<b>graftdir</b>	all files under <i>dir</i>

The patterns here are Unix-style “glob” patterns: \* matches any sequence of regular filename characters, ? matches any single regular filename character, and [range] matches any of the characters in *range* (e.g., a-z, a-zA-Z, a-f0-9\_.). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.

## 9. API Reference

See also

**New and changed setup.py arguments in setuptools** [<https://web.archive.org/web/20210614192516/https://setuptools.pypa.io/en/stable/userguide/keywords.html>]

The `setuptools` project adds new capabilities to the `setup` function and other APIs, makes the API consistent across different Python versions, and is hence recommended over using `distutils` directly.

Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

### 9.1. `distutils.core` — Core Distutils functionality

The `distutils.core` module is the only module that needs to be installed to use the Distutils. It provides the `setup()` (which is called from the setup script). Indirectly provides the `distutils.dist.Distribution` and `distutils.cmd.Command` class.

`distutils.core.setup(arguments)`

The basic do-everything function that does most everything you could ever ask for from a Distutils method.

The `setup` function takes a large number of arguments. These

are laid out in the following table.

argument name
<code>distutils.name</code>
<code>distutils.version</code>
<code>distutils.description</code>
<code>distutils.author</code>
<code>distutils.author_email</code>
<code>distutils.maintainer</code>
<code>distutils.maintainer_email</code>
<code>distutils.url</code>
<code>distutils.download</code>
<code>distutils.packages</code>
<code>distutils.modules</code>
<code>distutils.scripts</code>
<code>distutils.extensions</code>
<code>distutils.categories</code>
<code>distutils.classifiers</code>
<code>distutils.setup_name</code>
<code>distutils.setup_args</code>
<code>distutils.options</code>
<code>distutils.license</code>
<code>distutils.metadata</code>
<code>distutils.strings</code>
<code>distutils.commands</code>
<code>distutils.data_files</code>
<code>distutils.dirs</code>

```
distutils.core.run_setup(script_name[, script_args = None,
stop_after = 'run'])
```

Run a setup script in a somewhat controlled environment, and return the `distutils.dist.Distribution` instance that drives things. This is useful if you need to find out the

distribution meta-data (passed as keyword args from *script* to `setup()`), or the contents of the config files or command-line.

*script\_name* is a file that will be read and run with `exec()`. `sys.argv[0]` will be replaced with *script* for the duration of the call. *script\_args* is a list of strings; if supplied, `sys.argv[1:]` will be replaced by *script\_args* for the duration of the call.

*stop\_after* tells `setup()` when to stop processing; possible values:

### **description**

---

~~Stop~~ after the `Distribution` instance has been created and populated with the keyword arguments to `setup()`

---

~~Stop~~ after config files have been parsed (and their data stored in the `Distribution` instance)

---

~~Stop~~ after the command-line (`sys.argv[1:]` or *script\_args*) have been parsed (and the data stored in the `Distribution` instance.)

---

~~Stop~~ after all commands have been run (the same as if `setup()` had been called in the usual way). This is the default value.

---

In addition, the `distutils.core` module exposed a number of classes that live elsewhere.

- **Extension** from `distutils.extension`
- **Command** from `distutils.cmd`
- **Distribution** from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.

*class* `distutils.core.Extension`

The `Extension` class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor:

---

### **argument name**

---

~~list of filenames~~ **fullname** name of the extension, including any packages — ie. *not* a filename or pathname, but Python dotted name ~~list of filenames~~ **listfiles** filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the **build\_ext** command as source for a Python extension.

~~list of filenames~~ **listheaderfiles** filenames to search for C/C++ header files (in Unix form for portability)

~~list of macros~~ **listmacros** macros to define; each macro is defined using a 2-tuple (name, value), where *value* is either the string to define it to or None to define it without a particular value (equivalent of #define FOO in source or -DFOO on Unix C compiler command line)

~~list of macros~~ **listundefs** macros to undefine explicitly

~~list of filenames~~ **library\_dirs** filenames to search for C/C++ libraries at link time

~~list of filenames~~ **library\_dirs\_r** filenames (not filenames or paths) to link against

~~list of filenames~~ **library\_dirs\_run** filenames to search for C/C++ libraries at run time (for shared extensions, this is when the extension is loaded)

~~list of filenames~~ **library\_dirs\_run\_time** filenames to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

~~list of filenames~~ **library\_dirs\_run\_time** filenames to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

~~list of filenames~~ **library\_dirs\_run\_time** filenames to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

~~list of symbols~~ **library\_dirs\_run\_time** filenames to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

~~list of symbols~~ **library\_dirs\_run\_time** filenames to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

~~list of symbols~~ **library\_dirs\_run\_time** filenames to link with (eg. object files not implied by 'sources', static library that must be explicitly specified, binary resource files, etc.)

detected from the source extensions if not provided.  
~~options~~ specifies that a build failure in the extension should not  
abort the build process, but simply skip the extension.

---

*Changed in version 3.8:* On Unix, C extensions are no longer linked to libpython except on Android and Cygwin.

*class* distutils.core.Distribution

A **Distribution** describes how to build, install and package up a Python software package.

See the **setup()** function for a list of keyword arguments accepted by the Distribution constructor. **setup()** creates a Distribution instance.

*Changed in version 3.7:* **Distribution** now warns if classifiers, keywords and platforms fields are not specified as a list or a string.

*class* distutils.core.Command

A **Command** class (or rather, an instance of one of its subclasses) implement a single distutils command.

## 9.2. **distutils.ccompiler** — CCompiler base class

This module provides the abstract base class for the **CCompiler** classes. A **CCompiler** instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

`distutils.ccompiler.gen_lib_options(compiler, library_dirs,  
runtime_library_dirs, libraries)`

Generate linker options for searching library directories and linking with specific libraries. *libraries* and *library\_dirs* are,

respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

`distutils.ccompiler.gen_preprocess_options(macros, include_dirs)`

Generate C pre-processor options (`-D`, `-U`, `-I`) as used by at least two types of compilers: the typical Unix compiler and Visual C++. *macros* is the usual thing, a list of 1- or 2-tuples, where `(name,)` means undefine (`-U`) macro *name*, and `(name, value)` means define (`-D`) macro *name* to *value*. *include\_dirs* is just a list of directory names to be added to the header file search path (`-I`). Returns a list of command-line options suitable for either Unix compilers or Visual C++.

`distutils.ccompiler.get_default_compiler(osname, platform)`

Determine the default compiler to use for the given platform.

*osname* should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and *platform* the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

`distutils.ccompiler.new_compiler(plat=None, compiler=None, verbose=0, dry_run=0, force=0)`

Factory function to generate an instance of some `CCompiler` subclass for the supplied platform/compiler combination. *plat* defaults to `os.name` (eg. `'posix'`, `'nt'`), and *compiler* defaults to the default compiler for that platform. Currently only `'posix'` and `'nt'` are supported, and the default compilers are “traditional Unix interface” (**`UnixCCompiler`** class) and Visual C++ (**`MSVCCompiler`** class). Note that it's perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for *compiler*, *plat* is ignored.

`distutils.ccompiler.show_compilers()`

Print list of available compilers (used by the **--help-compiler** options to **build**, **build\_ext**, **build\_clib**).

`class distutils.ccompiler.CCompiler([verbose=0, dry_run=0, force=0])`

The abstract base class **CCompiler** defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.

The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are *verbose* (show verbose output), *dry\_run* (don't actually execute the steps) and *force* (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don't want to instantiate **CCompiler** or one of its subclasses directly - use the **distutils.CCompiler.new\_compiler()** factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

`add_include_dir(dir)`

Add *dir* to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to **add\_include\_dir()**.

`set_include_dirs(dirs)`

Set the list of directories that will be searched to *dirs* (a list of strings). Overrides any preceding calls to `add_include_dir()`; subsequent calls to `add_include_dir()` add to the list passed to `set_include_dirs()`. This does not affect any list of standard include directories that the compiler may search by default.

### `add_library(libname)`

Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to `add_library()` and/or `set_libraries()`. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

### `set_libraries(libnames)`

Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

### `add_library_dir(dir)`

Add *dir* to the list of directories that will be searched for libraries specified to `add_library()` and `set_libraries()`. The linker will be instructed to search for libraries in the order they are supplied to `add_library_dir()` and/or `set_library_dirs()`.

### `set_library_dirs(dirs)`

Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the linker may search by default.

`add_runtime_library_dir(dir)`

Add *dir* to the list of directories that will be searched for shared libraries at runtime.

`set_runtime_library_dirs(dirs)`

Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

`define_macro(name[, value = None])`

Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used.

`undefine_macro(name)`

Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by `define_macro()` and undefined by `undefine_macro()` the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to `compile()`), then that takes precedence.

`add_link_object(object)`

Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler object.

`set_link_objects(objects)`

Set the list of object files (or analogues) to be included in every link to *objects*. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU **autoconf**.

`detect_language(sources)`

Detect the language of a given file, or list of files. Uses the instance attributes **language\_map** (a dictionary), and **language\_order** (a list) to do the job.

`find_library_file(dirs, lib[, debug=0])`

Search the specified list of directories for a static or shared library file *lib* and return the full path to that file. If *debug* is true, look for a debugging version (if that makes sense on the current platform). Return `None` if *lib* wasn't found in any of the specified directories.

`has_function(funcname[, includes=None, include_dirs=None, libraries=None, library_dirs=None])`

Return a boolean indicating whether *funcname* is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

`library_dir_option(dir)`

Return the compiler option to add *dir* to the list of directories searched for libraries.

`library_option(lib)`

Return the compiler option to add *lib* to the list of libraries linked into the shared library or executable.

`runtime_library_dir_option(dir)`

Return the compiler option to add *dir* to the list of directories searched for runtime libraries.

`set_executables(**args)`

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the ‘executables’ class attribute), but most will have:

description
<code>compiler</code> C++ compiler
<code>linker_so</code> linker used to create shared objects and libraries
<code>linker_exe</code> linker used to create binary executables
<code>stratiblib</code> library creator

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See

[`distutils.util.split\_quoted\(\)`](#).)

The following methods invoke stages in the build process.

`compile(sources[, output_dir = None, macros = None, include_dirs = None, debug = 0, extra_preargs = None, extra_postargs = None, depends = None])`

Compile one or more source files. Generates object files (e.g. transforms a `.c` file to a `.o` file.)

*sources* must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg.

**MSVCCompiler** can handle resource files in *sources*). Return a list of object filenames, one per source filename in *sources*. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If *output\_dir* is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if *output\_dir* is *build*, then it would compile to `build/foo/bar.o`.

*macros*, if given, must be a list of macro definitions. A macro definition is either a (name, value) 2-tuple or a (name,) 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

*include\_dirs*, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

*debug* is a boolean; if true, the compiler will be instructed to output debug symbols in (or alongside) the object file(s).

*extra\_preargs* and *extra\_postargs* are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn't cut the mustard.

*depends*, if given, is a list of filenames that all targets depend on. If a source file is older than any file in

depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises **CompileError** on failure.

```
create_static_lib(objects, output_libname[, output_dir=None,
debug=0, target_lang=None])
```

Link a bunch of stuff together to create a static library file. The “bunch of stuff” consists of the list of object files supplied as *objects*, the extra object files supplied to `add_link_object()` and/or `set_link_objects()`, the libraries supplied to `add_library()` and/or `set_libraries()`, and the libraries supplied as *libraries* (if any).

*output\_libname* should be a library name, not a filename; the filename will be inferred from the library name. *output\_dir* is the directory where the library file will be put.

*debug* is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the compile step where this matters: the *debug* flag is included here just for consistency).

*target\_lang* is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises **LibError** on failure.

```
link(target_desc, objects, output_filename[, output_dir=None,
libraries=None, library_dirs=None, runtime_library_dirs=None,
export_symbols=None, debug=0, extra_preargs=None,
extra_postargs=None, build_temp=None, target_lang=None])
```

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as *objects*. *output\_filename* should be a filename. If *output\_dir* is supplied, *output\_filename* is relative to it (i.e. *output\_filename* can provide directory components if needed).

*libraries* is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. *foo* becomes *libfoo.a* on Unix and *foo.lib* on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

*library\_dirs*, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to

`add_library_dir()` and/or

`set_library_dirs()`. *runtime\_library\_dirs* is a list of directories that will be embedded into the shared library and used to search for other shared libraries that *\*it\** depends on at run-time. (This may only be relevant on Unix.)

*export\_symbols* is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

*debug* is as for `compile()` and `create_static_lib()`, with the slight distinction that it actually matters on most platforms (as opposed to `create_static_lib()`, which includes a *debug* flag mostly for form’s sake).

*extra\_preargs* and *extra\_postargs* are as for `compile()` (except of course that they supply command-line arguments for the particular linker being used).

*target\_lang* is the target language for which the given

objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises **LinkError** on failure.

```
link_executable(objects, output_progname[, output_dir=None,
libraries=None, library_dirs=None, runtime_library_dirs=None,
debug=0, extra_preargs=None, extra_postargs=None,
target_lang=None])
```

Link an executable. *output\_progname* is the name of the file executable, while *objects* are a list of object filenames to link in. Other arguments are as for the [link\(\)](#) method.

```
link_shared_lib(objects, output_libname[, output_dir=None,
libraries=None, library_dirs=None, runtime_library_dirs=None,
export_symbols=None, debug=0, extra_preargs=None,
extra_postargs=None, build_temp=None, target_lang=None])
```

Link a shared library. *output\_libname* is the name of the output library, while *objects* is a list of object filenames to link in. Other arguments are as for the [link\(\)](#) method.

```
link_shared_object(objects, output_filename[, output_dir=None,
libraries=None, library_dirs=None, runtime_library_dirs=None,
export_symbols=None, debug=0, extra_preargs=None,
extra_postargs=None, build_temp=None, target_lang=None])
```

Link a shared object. *output\_filename* is the name of the shared object that will be created, while *objects* is a list of object filenames to link in. Other arguments are as for the [link\(\)](#) method.

```
preprocess(source[, output_file=None, macros=None,
include_dirs=None, extra_preargs=None,
extra_postargs=None])
```

Preprocess a single C/C++ source file, named in

*source*. Output will be written to file named *output\_file*, or *stdout* if *output\_file* not supplied. *macros* is a list of macro definitions as for `compile()`, which will augment the macros set with `define_macro()` and `undefine_macro()`. *include\_dirs* is a list of directory names that will be added to the default list, in the same way as `add_include_dir()`.

Raises **PreprocessError** on failure.

The following utility methods are defined by the `CCompiler` class, for use by the various concrete subclasses.

`executable_filename(basename[, strip_dir=0, output_dir=""])`

Returns the filename of the executable for the given *basename*. Typically for non-Windows platforms this is the same as the *basename*, while Windows will get a `.exe` added.

`library_filename(libname[, lib_type='static', strip_dir=0, output_dir=""])`

Returns the filename for the given library name on the current platform. On Unix a library with *lib\_type* of `'static'` will typically be of the form `liblibname.a`, while a *lib\_type* of `'dynamic'` will be of the form `liblibname.so`.

`object_filenames(source_filenames[, strip_dir=0, output_dir=""])`

Returns the name of the object files for the given source files. *source\_filenames* should be a list of filenames.

`shared_object_filename(basename[, strip_dir=0, output_dir=""])`

Returns the name of a shared object file for the given file name *basename*.

`execute(func, args[, msg=None, level=1])`

Invokes `distutils.util.execute()`. This method

invokes a Python function *func* with the given arguments *args*, after logging and taking into account the *dry\_run* flag.

`spawn(cmd)`

Invokes `distutils.util.spawn()`. This invokes an external process to run the given command.

`mkpath(name[, mode=511])`

Invokes `distutils.dir_util.mkpath()`. This creates a directory and any missing ancestor directories.

`move_file(src, dst)`

Invokes `distutils.file_util.move_file()`. Renames *src* to *dst*.

`announce(msg[, level=1])`

Write a message using `distutils.log.debug()`.

`warn(msg)`

Write a warning message *msg* to standard error.

`debug_print(msg)`

If the *debug* flag is set on this `CCompiler` instance, print *msg* to standard output, otherwise do nothing.

## 9.3. `distutils.unixccompiler` — Unix C Compiler

This module provides the `UnixCCompiler` class, a subclass of `CCompiler` that handles the typical Unix-style command-line C compiler:

- macros defined with `-Dname[=value]`

- macros undefined with **-Uname**
- include search directories specified with **-Idir**
- libraries specified with **-llib**
- library search directories specified with **-Ldir**
- compile handled by **cc** (or similar) executable with **-c** option: compiles **.c** to **.o**
- link static library handled by **ar** command (possibly with **ranlib**)
- link shared library handled by **cc -shared**

## 9.4. **distutils.msvccompiler** — Microsoft Compiler

This module provides **MSVCCompiler**, an implementation of the abstract **CCompiler** class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003.

**MSVCCompiler** will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables *DISTUTILS\_USE\_SDK* and *MSSdk* must be both set. *MSSdk* indicates that the current environment has been setup by the SDK's *SetEnv.Cmd* script, or that the environment variables had been registered when the SDK was installed; *DISTUTILS\_USE\_SDK* indicates that the distutils user has made an explicit choice to override the compiler selection by **MSVCCompiler**.

## 9.5. **distutils.bcppcompiler** — Borland Compiler

This module provides **BorlandCCompiler**, a subclass of the abstract **CCompiler** class for the Borland C++ compiler.

## 9.6. **distutils.cygwincompiler** — Cygwin Compiler

This module provides the **CygwinCCompiler** class, a subclass of **UnixCCompiler** that handles the Cygwin port of the GNU C compiler to Windows. It also contains the **Mingw32CCompiler** class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).

## 9.7. **distutils.archive\_util** — Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

`distutils.archive_util.make_archive(base_name, format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])`

Create an archive file (eg. zip or tar). *base\_name* is the name of the file to create, minus any format-specific extension; *format* is the archive format: one of zip, tar, gztar, bztar, xztar, or ztar. *root\_dir* is a directory that will be the root directory of the archive; ie. we typically `chdir` into *root\_dir* before creating the archive. *base\_dir* is the directory where we start archiving from; ie. *base\_dir* will be the common prefix of all files and directories in the archive. *root\_dir* and *base\_dir* both default to the current directory. Returns the name of the archive file.

*Changed in version 3.5:* Added support for the `xztar` format.

`distutils.archive_util.make_tarball(base_name, base_dir[, compress='gzip', verbose=0, dry_run=0])`

‘Create an (optional compressed) archive as a tar file from all files in and under *base\_dir*. *compress* must be ‘gzip’ (the default), ‘bzip2’, ‘xz’, ‘compress’, or None. For the ‘compress’ method the compression utility named by **compress** must be on the default program search path, so this is probably Unix-specific. The output tar file will be named *base\_dir.tar*, possibly plus the appropriate compression extension (`.gz`, `.bz2`, `.xz` or `.Z`). Return the output

filename.

*Changed in version 3.5:* Added support for the `xz` compression.

`distutils.archive_util.make_zipfile(base_name, base_dir[, verbose=0, dry_run=0])`

Create a zip file from all files in and under *base\_dir*. The output zip file will be named *base\_name* + `.zip`. Uses either the `zipfile` Python module (if available) or the InfoZIP `zip` utility (if installed and found on the default search path). If neither tool is available, raises `DistutilsExecError`. Returns the name of the output zip file.

## 9.8. `distutils.dep_util` — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

`distutils.dep_util.newer(source, target)`

Return true if *source* exists and is more recently modified than *target*, or if *source* exists and *target* doesn't. Return false if both exist and *target* is the same age or newer than *source*. Raise `DistutilsFileError` if *source* does not exist.

`distutils.dep_util.newer_pairwise(sources, targets)`

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (*sources*, *targets*) where source is newer than target, according to the semantics of `newer()`.

`distutils.dep_util.newer_group(sources, target[, missing='error'])`

Return true if *target* is out-of-date with respect to any file listed in *sources*. In other words, if *target* exists and is newer

than every file in *sources*, return false; otherwise return true. *missing* controls what we do when a source file is missing; the default ('error') is to blow up with an **OSError** from inside **os.stat()**; if it is 'ignore', we silently drop any missing source files; if it is 'newer', any missing source files make us assume that *target* is out-of-date (this is handy in “dry-run” mode: it’ll make you pretend to carry out commands that wouldn’t work because inputs are missing, but that doesn’t matter because you’re not actually going to run the commands).

## 9.9. **distutils.dir\_util** — Directory tree operations

This module provides functions for operating on directories and trees of directories.

**distutils.dir\_util.mkpath**(*name*[, *mode* = 0o777, *verbose* = 0, *dry\_run* = 0])

Create a directory and any missing ancestor directories. If the directory already exists (or if *name* is the empty string, which means the current directory, which of course exists), then do nothing. Raise **DistutilsFileError** if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If *verbose* is true, print a one-line summary of each **mkdir** to stdout. Return the list of directories actually created.

**distutils.dir\_util.create\_tree**(*base\_dir*, *files*[, *mode* = 0o777, *verbose* = 0, *dry\_run* = 0])

Create all the empty directories under *base\_dir* needed to put *files* there. *base\_dir* is just the name of a directory which doesn’t necessarily exist yet; *files* is a list of filenames to be interpreted relative to *base\_dir*. *base\_dir* + the directory portion of every file in *files* will be created if it doesn’t already exist. *mode*, *verbose* and *dry\_run* flags are as for **mkpath()**.

```
distutils.dir_util.copy_tree(src, dst[, preserve_mode=1,
preserve_times=1, preserve_symlinks=0, update=0, verbose=0,
dry_run=0])
```

Copy an entire directory tree *src* to a new location *dst*. Both *src* and *dst* must be directory names. If *src* is not a directory, raise **DistutilsFileError**. If *dst* does not exist, it is created with `mkpath()`. The end result of the copy is that every file in *src* is copied to *dst*, and directories under *src* are recursively copied to *dst*. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by *update* or *dry\_run*: it is simply the list of all files under *src*, with the names changed to be under *dst*.

*preserve\_mode* and *preserve\_times* are the same as for `distutils.file_util.copy_file()`; note that they only apply to regular files, not to directories. If *preserve\_symlinks* is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. *update* and *verbose* are the same as for `copy_file()`.

Files in *src* that begin with `.nfs` are skipped (more information on these files is available in answer D2 of the [NFS FAQ page](http://nfs.sourceforge.net/#section_d1) [[http://nfs.sourceforge.net/#section\\_d1](http://nfs.sourceforge.net/#section_d1)]).

*Changed in version 3.3.1:* NFS files are ignored.

```
distutils.dir_util.remove_tree(directory[, verbose=0, dry_run=0])
```

Recursively remove *directory* and all files and directories underneath it. Any errors are ignored (apart from being reported to `sys.stdout` if *verbose* is true).

## 9.10. `distutils.file_util` — Single file operations

This module contains some utility functions for operating on individual files.

`distutils.file_util.copy_file(src, dst[, preserve_mode=1, preserve_times=1, update=0, link=None, verbose=0, dry_run=0])`

Copy file *src* to *dst*. If *dst* is a directory, then *src* is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If *preserve\_mode* is true (the default), the file's mode (type and permission bits, or whatever is analogous on the current platform) is copied. If *preserve\_times* is true (the default), the last-modified and last-access times are copied as well. If *update* is true, *src* will only be copied if *dst* does not exist, or if *dst* does exist but is older than *src*.

*link* allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to 'hard' or 'sym'; if it is `None` (the default), files are copied. Don't set *link* on systems that don't support it: `copy_file()` doesn't check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple (*dest\_name*, *copied*): *dest\_name* is the actual name of the output file, and *copied* is true if the file was copied (or would have been copied, if *dry\_run* true).

`distutils.file_util.move_file(src, dst[, verbose, dry_run])`

Move file *src* to *dst*. If *dst* is a directory, the file will be moved into it with the same name; otherwise, *src* is just renamed to *dst*. Returns the new full name of the file.

### Warning

Handles cross-device moves on Unix using `copy_file()`. What about other systems?

`distutils.file_util.write_file(filename, contents)`

Create a file called *filename* and write *contents* (a sequence of strings without line terminators) to it.

## 9.11. `distutils.util` — Miscellaneous other utility functions

This module contains other assorted bits and pieces that don't fit into any other utility module.

`distutils.util.get_platform()`

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific build distributions. Typically includes the OS name and version and the architecture (as supplied by `'os.uname()'`), although the exact information included depends on the OS; e.g., on Linux, the kernel version isn't particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`

For non-POSIX platforms, currently just returns `sys.platform`.

For macOS systems the OS version reflects the minimal version on which binaries will run (that is, the value of `MACOSX_DEPLOYMENT_TARGET` during the build of Python), not the OS version of the current system.

For universal binary builds on macOS the architecture value reflects the universal binary status instead of the architecture of the current processor. For 32-bit universal binaries the architecture is `fat`, for 64-bit universal binaries the architecture is `fat64`, and for 4-way universal binaries the architecture is `universal`. Starting from Python 2.7 and Python 3.2 the architecture `fat3` is used for a 3-way universal build (`ppc`, `i386`, `x86_64`) and `intel` is used for a universal build with the `i386` and `x86_64` architectures

Examples of returned values on macOS:

- `macosx-10.3-ppc`
- `macosx-10.3-fat`
- `macosx-10.5-universal`
- `macosx-10.6-intel`

For AIX, Python 3.9 and later return a string starting with “aix”, followed by additional fields (separated by ‘-’) that represent the combined values of AIX Version, Release and Technology Level (first field), Build Date (second field), and bit-size (third field). Python 3.8 and earlier returned only a single additional field with the AIX Version and Release.

Examples of returned values on AIX:

- `aix-5307-0747-32 # 32-bit build on AIX oslevel -s: 5300-07-00-0000`
- `aix-7105-1731-64 # 64-bit build on AIX oslevel -s: 7100-05-01-1731`
- `aix-7.2 # Legacy form reported in Python 3.8 and earlier`

*Changed in version 3.9:* The AIX platform string format now also includes the technology level, build date, and ABI bit-size.

`distutils.util.convert_path(pathname)`

Return ‘pathname’ as a name that will work on the native filesystem, i.e. split it on ‘/’ and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises [ValueError](#) on non-Unix-ish systems if *pathname* either starts or ends with a slash.

`distutils.util.change_root(new_root, pathname)`

Return *pathname* with *new\_root* prepended. If *pathname* is relative, this is equivalent to `os.path.join(new_root, pathname)` Otherwise, it requires making *pathname* relative and then joining the two,

which is tricky on DOS/Windows.

### `distutils.util.check_environ()`

Ensure that `os.environ` has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- **HOME** - user's home directory (Unix only)
- **PLAT** - description of the current platform, including hardware and OS (see `get_platform()`)

### `distutils.util.subst_vars(s, local_vars)`

Perform shell/Perl-style variable substitution on `s`. Every occurrence of `$` followed by a name is considered a variable, and variable is substituted by the value found in the `local_vars` dictionary, or in `os.environ` if it's not in `local_vars`. `os.environ` is first checked/augmented to guarantee that it contains certain values: see `check_environ()`. Raise `ValueError` for any variables not found in either `local_vars` or `os.environ`.

Note that this is not a full-fledged string interpolation function. A valid `$variable` can consist only of upper and lower case letters, numbers and an underscore. No `{ }` or `( )` style quoting is available.

### `distutils.util.split_quoted(s)`

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

### `distutils.util.execute(func, args[, msg=None, verbose=0, dry_run=0])`

Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the *dry\_run* flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

`distutils.util.strtobool(val)`

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises `ValueError` if *val* is anything else.

`distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])`

Byte-compile a collection of Python source files to `.pyc` files in a `__pycache__` subdirectory (see [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] and [PEP 488](https://peps.python.org/pep-0488/) [https://peps.python.org/pep-0488/]). *py\_files* is a list of files to compile; any files that don’t end in `.py` are silently skipped. *optimize* must be one of the following:

- 0 - don’t optimize
- 1 - normal optimization (like `python -O`)
- 2 - extra optimization (like `python -OO`)

If *force* is true, all files are recompiled regardless of timestamps.

The source filename encoded in each `bytecode` file defaults to the filenames listed in *py\_files*; you can modify these with *prefix* and *basedir*. *prefix* is a string that will be stripped off of each source filename, and *base\_dir* is a directory name that will be prepended (after *prefix* is stripped). You can supply either or both (or neither) of *prefix* and *base\_dir*, as you wish.

If `dry_run` is true, doesn't actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard `py_compile` module, or indirectly by writing a temporary script and executing it. Normally, you should let `byte_compile()` figure out to use direct compilation or not (see the source for details). The `direct` flag is used by the script generated in indirect mode; unless you know what you're doing, leave it set to `None`.

*Changed in version 3.2.3:* Create `.pyc` files with an `import magic tag` in their name, in a `__pycache__` subdirectory instead of files without tag in the current directory.

*Changed in version 3.5:* Create `.pyc` files according to [PEP 488](https://peps.python.org/pep-0488/) [https://peps.python.org/pep-0488/].

`distutils.util.rfc822_escape(header)`

Return a version of `header` escaped for inclusion in an [RFC 822](https://datatracker.ietf.org/doc/html/rfc822.html) header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.

## 9.12. `distutils.dist` — The Distribution class

This module provides the `Distribution` class, which represents the module distribution being built/installed/distributed.

## 9.13. `distutils.extension` — The Extension class

This module provides the `Extension` class, used to describe C/C++ extension modules in setup scripts.

## 9.14. `distutils.debug` — Distutils

## debug mode

This module provides the `DEBUG` flag.

### 9.15. `distutils.errors` — Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, `SystemExit` is usually raised for errors that are obviously the end-user's fault (eg. bad command-line arguments).

This module is safe to use in `from ... import *` mode; it only exports symbols whose names start with `Distutils` and end with `Error`.

### 9.16. `distutils.fancy_getopt` — Wrapper around the standard `getopt` module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

`distutils.fancy_getopt.fancy_getopt(options, negative_opt, object, args)`

Wrapper function. *options* is a list of (long\_option, short\_option, help\_string) 3-tuples as described in the constructor for `FancyGetopt`. *negative\_opt* should be a dictionary mapping option names to option names, both the key and value should be in the *options* list. *object* is an object

which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). *args* is the argument list. Will use `sys.argv[1:]` if you pass `None` as *args*.

`distutils.fancy_getopt.wrap_text(text, width)`

Wraps *text* to less than *width* wide.

`class distutils.fancy_getopt.FancyGetopt([option_table=None])`

The *option\_table* is a list of 3-tuples: (*long\_option*, *short\_option*, *help\_string*)

If an option takes an argument, its *long\_option* should have '=' appended; *short\_option* should just be a single character, no ':' in any case. *short\_option* should be `None` if a *long\_option* doesn't have a corresponding *short\_option*. All option tuples must have long options.

The `FancyGetopt` class provides the following methods:

`FancyGetopt.getopt([args=None, object=None])`

Parse command-line options in *args*. Store as attributes on *object*.

If *args* is `None` or not supplied, uses `sys.argv[1:]`. If *object* is `None` or not supplied, creates a new `OptionDummy` instance, stores option values there, and returns a tuple (*args*, *object*). If *object* is supplied, it is modified in place and `getopt()` just returns *args*; in both cases, the returned *args* is a modified copy of the passed-in *args* list, which is left untouched.

`FancyGetopt.get_option_order()`

Returns the list of (*option*, *value*) tuples processed by the previous run of `getopt()` Raises `RuntimeError` if `getopt()` hasn't been called yet.

`FancyGetopt.generate_help([header=None])`

Generate help text (a list of strings, one per suggested line of output) from the option table for this `FancyGetopt` object.

If supplied, prints the supplied *header* at the top of the help.

## 9.17. `distutils.filelist` — The `FileList` class

This module provides the `FileList` class, used for poking about the filesystem and building lists of files.

## 9.18. `distutils.log` — Simple PEP 282 [https://peps.python.org/pep-0282/] -style logging

## 9.19. `distutils.spawn` — Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a sub-process. Also provides `find_executable()` to search the path for a given executable name.

## 9.20. `distutils.sysconfig` — System configuration information

*Deprecated since version 3.10:* `distutils.sysconfig` has been merged into `sysconfig`.

The `distutils.sysconfig` module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the `Makefile` and configuration header that are installed

with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the `distutils` package.

`distutils.sysconfig.PREFIX`

The result of `os.path.normpath(sys.prefix)`.

`distutils.sysconfig.EXEC_PREFIX`

The result of `os.path.normpath(sys.exec_prefix)`.

`distutils.sysconfig.get_config_var(name)`

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

`distutils.sysconfig.get_config_vars(...)`

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a given name does not have a corresponding value, `None` will be included for that variable.

`distutils.sysconfig.get_config_h_filename()`

Return the full path name of the configuration header. For Unix, this will be the header generated by the **configure** script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

`distutils.sysconfig.get_makefile_filename()`

Return the full path name of the `Makefile` used to build Python. For Unix, this will be a file generated by the **configure** script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This

function is only useful on POSIX platforms.

The following functions are deprecated together with this module and they have no direct replacement.

`distutils.sysconfig.get_python_inc([plat_specific[, prefix]])`

Return the directory for either the general or platform-dependent C include files. If *plat\_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of `PREFIX`, or as the exec-prefix instead of `EXEC_PREFIX` if *plat\_specific* is true.

`distutils.sysconfig.get_python_lib([plat_specific[, standard_lib[, prefix]]])`

Return the directory for either the general or platform-dependent library installation. If *plat\_specific* is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If *prefix* is given, it is used as either the prefix instead of `PREFIX`, or as the exec-prefix instead of `EXEC_PREFIX` if *plat\_specific* is true. If *standard\_lib* is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the `distutils` package.

`distutils.sysconfig.customize_compiler(compiler)`

Do any platform-specific customization of a `distutils.ccompiler.CCompiler` instance.

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's `Makefile`. This information includes the selected compiler, compiler and linker options, and the

extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

`distutils.sysconfig.set_python_build()`

Inform the `distutils.sysconfig` module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.

## 9.21. `distutils.text_file` — The `TextFile` class

This module provides the `TextFile` class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

```
class distutils.text_file.TextFile([filename = None, file = None,
**options])
```

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as `#` is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

`TextFile` instances are create with either `filename`, `file`, or both. `RuntimeError` is raised if both are `None`. `filename` should be a string, and `file` a file object (or something that provides `readline()` and `close()` methods). It is

recommended that you supply at least *filename*, so that **TextFile** can include it in warning messages. If *file* is not supplied, **TextFile** creates its own using the **open()** built-in function.

The options are all boolean, and affect the values returned by **readline()**

### **def options:**

**strip\_comments** '#' to end-of-line, as well as any whitespace leading up to the '#'—unless it is escaped by a backslash  
**rstrip\_ws** leading whitespace from each line before returning it  
**rstrip\_ws** trailing whitespace (including line terminator!) from each line before returning it.

**skip\_blanks** that are empty \*after\* stripping comments and whitespace. (If both **rstrip\_ws** and **rstrip\_ws** are false, then some lines may consist of solely whitespace: these will \*not\* be skipped, even if **skip\_blanks** is true.)

**join\_lines** backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N + 1 physical lines will be joined to form one logical line.

**rstrip\_ws** leading whitespace from lines that are joined to their predecessor; only matters if (**join\_lines** and not **rstrip\_ws**)

Note that since **rstrip\_ws** can strip the trailing newline, the semantics of **readline()** must differ from those of the built-in file object's **readline()** method! In particular, **readline()** returns **None** for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if **rstrip\_ws** is true but **skip\_blanks** is not.

**open(filename)**

Open a new file *filename*. This overrides any *file* or *filename* constructor arguments.

**close()**

Close the current file and forget everything we know

about it (including the filename and the current line number).

`warn(msg[, line = None])`

Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as "lines 3-5". If *line* is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

`readline()`

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with `unreadline()`). If the *join\_lines* option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling `warn()` after `readline()` emits a warning about the physical line(s) just read. Returns `None` on end-of-file, since the empty string can occur if *rstrip\_ws* is true but *strip\_blanks* is not.

`readlines()`

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

`unreadline(line)`

Push *line* (a string) onto an internal buffer that will be checked by future `readline()` calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread” with `unreadline()` are not subsequently re-cleansed (whitespace stripped, or whatever) when read with `readline()`. If multiple calls are made to `unreadline()` before a call to `readline()`, the lines will be returned most in most

recent first order.

## 9.22. `distutils.version` — Version number classes

## 9.23. `distutils.cmd` — Abstract base class for Distutils commands

This module supplies the abstract base class `Command`.

```
class distutils.cmd.Command(dist)
```

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called *options*. The options are declared in

`initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument *dist*, a `Distribution` instance.

## 9.24. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same

name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you'd copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it's implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `Command` must define the following methods.

#### `Command.initialize_options()`

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

#### `Command.finalize_options()`

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to code option dependencies: if `foo` depends on `bar`, then it is safe to set `foo` from `bar` as long as `foo` still has the same value it was assigned in `initialize_options()`.

#### `Command.run()`

A command's raison d'être: carry out the action it exists to perform, controlled by the options initialized in `initialize_options()`, customized by other commands, the setup script, the command-line, and config files, and finalized in `finalize_options()`. All terminal output and filesystem interaction should be done by `run()`.

#### `Command.sub_commands`

*sub\_commands* formalizes the notion of a “family” of

commands, e.g. `install` as the parent with sub-commands `install_lib`, `install_headers`, etc. The parent of a family of commands defines *sub\_commands* as a class attribute; it's a list of 2-tuples `(command_name, predicate)`, with *command\_name* a string and *predicate* a function, a string or `None`. *predicate* is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (E.g. `install_headers` is only applicable if we have any C header files to install.) If *predicate* is `None`, that command is always applicable.

*sub\_commands* is usually defined at the *end* of a class, because predicates can be methods of the class, so they must already have been defined. The canonical example is the `install` command.

## 9.25. `distutils.command` — Individual Distutils commands

### 9.26. `distutils.command.bdist` — Build a binary installer

### 9.27. `distutils.command.bdist_packager` — Abstract base class for packagers

### 9.28. `distutils.command.bdist_dumb` — Build a “dumb” installer

### 9.29. `distutils.command.bdist_rpm` — Build a binary distribution as a Redhat RPM and SRPM

**9.30. `distutils.command.sdist` — Build a source distribution**

**9.31. `distutils.command.build` — Build all files of a package**

**9.32. `distutils.command.build_clib` — Build any C libraries in a package**

**9.33. `distutils.command.build_ext` — Build any extensions in a package**

**9.34. `distutils.command.build_py` — Build the .py/.pyc files of a package**

*class* `distutils.command.build_py.build_py`

*class* `distutils.command.build_py.build_py_2to3`

Alternative implementation of `build_py` which also runs the 2to3 conversion library on each .py file that is going to be installed. To use this in a `setup.py` file for a distribution that is designed to run with both Python 2.x and 3.x, add:

```
try:
 from distutils.command.build_py import build_py
except ImportError:
 from distutils.command.build_py import build_py
```

to your `setup.py`, and later:

```
cmdclass = {'build_py': build_py}
```

to the invocation of `setup()`.

9.35.

**`distutils.command.build_scripts`** —  
Build the scripts of a package

9.36. **`distutils.command.clean`** —  
Clean a package build area

This command removes the temporary files created by **build** and its subcommands, like intermediary compiled object files. With the `--all` option, the complete build directory will be removed.

Extension modules built **in place** will not be cleaned, as they are not in the build directory.

9.37. **`distutils.command.config`** —  
Perform package configuration

9.38. **`distutils.command.install`** —  
Install a package

9.39.

**`distutils.command.install_data`** —  
Install data files from a package

9.40.

**`distutils.command.install_headers`**  
— Install C/C++ header files from a package

9.41.

**`distutils.command.install_lib`** —

## Install library files from a package

9.42.

**`distutils.command.install_scripts`**

— Install script files from a package

9.43. **`distutils.command.register`** —  
Register a module with the Python  
Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in [PEP 301](https://peps.python.org/pep-0301/) [https://peps.python.org/pep-0301/].

9.44. **`distutils.command.check`** —  
Check the meta-data of a package

The `check` command performs some tests on the meta-data of a package. For example, it verifies that all required meta-data are provided as the arguments passed to the `setup()` function.

# Installing Python Modules (Legacy version)

Author

Greg Ward

## Note

The entire `distutils` package has been deprecated and will be removed in Python 3.12. This documentation is retained as a reference only, and will be removed with the package. See the [What's New](#) entry for more information.

## See also

### Installing Python Modules

The up to date module installation documentation. For regular Python usage, you almost certainly want that document rather than this one.

## Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

## Note

This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure

alternatives. Refer to the [quick recommendations section](https://packaging.python.org/guides/tool-recommendations/) [https://packaging.python.org/guides/tool-recommendations/] in the Python Packaging User Guide for more information.

## Introduction

In Python 2.0, the `distutils` API was first added to the standard library. This provided Linux distro maintainers with a standard way of converting Python projects into Linux distro packages, and system administrators with a standard way of installing them directly onto target systems.

In the many years since Python 2.0 was released, tightly coupling the build system and package installer to the language runtime release cycle has turned out to be problematic, and it is now recommended that projects use the `pip` package installer and the `setuptools` build system, rather than using `distutils` directly.

See [Installing Python Modules](#) and [Distributing Python Modules](#) for more details.

This legacy documentation is being retained only until we're confident that the `setuptools` documentation covers everything needed.

## Distutils based source distributions

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running one command from a terminal:

```
python setup.py install
```

For Windows, this command should be run from a command prompt window (*Start ▶ Accessories*):

```
setup.py install
```

If all these things are true, then you already know how to build and install the modules you've just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don't really need this manual. Or rather, the above command is everything you need to get out of this manual.

## Standard Build and Install

As described in section [Distutils based source distributions](#), building and installing a module distribution using the Distutils is usually one simple command to run from a terminal:

```
python setup.py install
```

### Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution `foo-1.0.tar.gz` onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf - # unpacks into di
cd foo-1.0
python setup.py install
```

On Windows, you'd probably download `foo-1.0.zip`. If you downloaded the archive file to `C:\Temp`, then it would unpack into `C:\Temp\foo-1.0`; you can use either an archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as **unzip** or **pkunzip**) to unpack the archive. Then, open a command prompt window and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```

## Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```
python setup.py build
python setup.py install
```

If you do this, you will notice that running the **install** command first runs the **build** command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

## How building works

As implied above, the **build** command is responsible for putting the files to install into a *build directory*. By default, this is `build` under the distribution root; if you’re excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the **--build-base** option. For example:

```
python setup.py build --build-base=/path/to/pybuild/foo-
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section [Distutils Configuration Files](#).) Normally, this isn't necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
 temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.plat` directory holds temporary files generated by the compile/link process that don't actually get installed. In either case, the `lib` (or `lib.plat`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.

## How installation works

After the **build** command runs (whether you run it explicitly, or the **install** command does it for you), the work of the **install** command is relatively simple: all it has to do is copy everything under `build/lib` (or `build/lib.plat`) to your chosen installation directory.

If you don't choose an installation directory—i.e., if you just run `setup.py install`—then the **install** command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and macOS, which is also Unix-based), it also depends on

whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

### **Module installation location**

---

**(Pure)** lib/pythonX.Y/site-packages

---

**(Non-pure)** lib/pythonX.Y/site-packages

---

**Windows** \X.Y\lib\packages

---

Notes:

1. Most Linux distributions include Python as a standard part of the system, so *prefix* and *exec-prefix* are usually both /usr on Linux. If you build Python yourself on Linux (or any Unix-like system), the default *prefix* and *exec-prefix* are /usr/local.
2. The default installation directory on Windows was C:\Program Files\Python under Python 1.6a1, 1.5.2, and earlier.

*prefix* and *exec-prefix* stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and macOS. You can find out what your Python installation uses for *prefix* and *exec-prefix* by running Python in interactive mode and typing a few simple commands. Under Unix, just type `python` at the shell prompt. Under Windows, choose *Start* ▸ *Programs* ▸ *Python X.Y* ▸ *Python (command line)*. Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my *prefix* and *exec-prefix*:

```
Python 2.4 (#26, Aug 7 2004, 17:19:02)
```

```
Type "help", "copyright", "credits" or "license" for more
```

```
>>> import sys
```

```
>>> sys.prefix
```

```
'/usr'
```

```
>>> sys.exec_prefix
```

```
'/usr'
```

A few other placeholders are used in this document: *X.Y* stands for

the version of Python, for example `3.2`; `abiflags` will be replaced by the value of `sys.abiflags` or the empty string for platforms which don't define ABI flags; `distname` will be replaced by the name of the module distribution being installed. Dots and capitalization are important in the paths; for example, a value that uses `python3.2` on UNIX will typically use `Python32` on Windows.

If you don't want to install modules to the standard location, or if you don't have permission to write there, then you need to read about alternate installations in section [Alternate Installation](#). If you want to customize your installation directories more heavily, see section [Custom Installation](#) on custom installations.

## Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils **install** command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the **install** command picks a set of directories (called an *installation scheme*) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Note that the various alternate installation schemes are mutually exclusive: you can pass `--user`, or `--home`, or `--prefix` and `--exec-prefix`, or `--install-base` and `--install-platbase`, but you can't mix from these groups.

### Alternate installation: the user scheme

This scheme is designed to be the most convenient solution for users that don't have write permission to the global site-packages directory or don't want to install into it. It is enabled with a simple option:

```
python setup.py install --user
```

Files will be installed into subdirectories of `site.USER_BASE` (written as *userbase* hereafter). This scheme installs pure Python modules and extension modules in the same location (also known as `site.USER_SITE`). Here are the values for UNIX, including macOS:

#### Installation directory

<b>modules</b>	<code>userbase/lib/pythonX.Y/site-packages</code>
----------------	---------------------------------------------------

<b>scripts</b>	<code>userbase/bin</code>
----------------	---------------------------

<b>data</b>	<code>userbase</code>
-------------	-----------------------

<b>Cheaders</b>	<code>userbase/include/pythonX.Yabi/flags/distname</code>
-----------------	-----------------------------------------------------------

And here are the values used on Windows:

#### Installation directory

<b>modules</b>	<code>userbase\PythonXY\site-packages</code>
----------------	----------------------------------------------

<b>scripts</b>	<code>userbase\PythonXY\Scripts</code>
----------------	----------------------------------------

<b>data</b>	<code>userbase</code>
-------------	-----------------------

<b>Cheaders</b>	<code>userbase\PythonXY\Include{distname}</code>
-----------------	--------------------------------------------------

The advantage of using this scheme compared to the other ones described below is that the user site-packages directory is under normal conditions always included in `sys.path` (see `site` for more information), which means that there is no additional step to perform after running the `setup.py` script to finalize the installation.

The `build_ext` command also has a `--user` option to add `userbase/include` to the compiler search path for header files and `userbase/lib` to the compiler search path for libraries as well as to the runtime search path for shared C libraries (`rpath`).

## Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme’s name is derived from the idea of a “home” directory on Unix, since it’s not unusual for a Unix user to make their home directory have a layout similar to `/usr/` or `/usr/local/`. This scheme can be used by anyone, regardless of the operating system they are installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the **--home** option. On Unix, lazy typists can just type a tilde (`~`); the **install** command will expand this to your home directory:

```
python setup.py install --home=~
```

To make Python find the distributions installed with this scheme, you may have to [modify Python’s search path](#) or edit **sitecustomize** (see [site](#)) to call **site.addsitedir()** or edit [sys.path](#).

The **--home** option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

#### **Installation directory**

---

<code>module</code>	<code>site-packages/python</code>
---------------------	-----------------------------------

---

<code>scripts</code>	<code>bin</code>
----------------------	------------------

---

<code>data</code>	
-------------------	--

---

<code>headers</code>	<code>include/python/distname</code>
----------------------	--------------------------------------

---

(Mentally replace slashes with backslashes if you’re on Windows.)

## **Alternate installation: Unix (the prefix scheme)**

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—

that's why the user and home schemes come before. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in `/usr/local/lib/python2.X` rather than `/usr/lib/python2.X`. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.X`, but those modules would have to be installed to, say, `/mnt/@server/export/lib/python2.X`. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt/@se
```

In either case, the **--prefix** option defines the installation base, and the **--exec-prefix** option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If **--exec-prefix** is not supplied, it defaults to **--prefix**. Files are installed as follows:

#### **Installation directory**

---

Python modules	<code>pythonX.Y/site-packages</code>
----------------	--------------------------------------

---

extension modules	<code>lib/pythonX.Y/site-packages</code>
-------------------	------------------------------------------

---

scripts	<code>usr/bin</code>
---------	----------------------

---

data	
------	--

---

C headers	<code>include/pythonX.Yabi/flags/distname</code>
-----------	--------------------------------------------------

---

There is no requirement that **--prefix** or **--exec-prefix** actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation

time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with **--prefix** and **--exec-prefix** supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll never use the prefix scheme, but every time you run `python setup.py install` without any other options, you're using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your **--prefix** and **--exec-prefix** don't even point to an alternate Python installation, this is immaterial.)

## Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user's home directory, and since the standard Python installation under Windows is simpler than under Unix, the **--prefix** option has traditionally been used to install additional packages in separate locations on Windows.

```
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the **--prefix** option; the **--exec-prefix** option is not supported under Windows, which means that pure Python modules and extension modules are installed into the same location. Files are installed as follows:

### Installation directory

---

modules	\Lib\site-packages
---------	--------------------

---

scripts	\Scripts
---------	----------

---

`datafix`

`Cheaders``Include{distname}`

---

## Custom Installation

Sometimes, the alternate installation schemes described in section [Alternate Installation](#) just don't do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you're creating a *custom installation scheme*.

To create a custom installation scheme, you start with one of the alternate schemes and override some of the installation directories used for the various types of files, using these options:

### Override Option

---

Python modules	<code>relib</code>
extension modules	<code>lib</code>
all modules	<code>-lib</code>
scripts	<code>install-scripts</code>
data	<code>install-data</code>
C headers	<code>all-headers</code>

---

These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same—they only differ when you use the Unix “prefix scheme” and supply different `--prefix` and `--exec-prefix` options; using `--install-lib` will override values computed or given for `--install-purelib` and `--install-platlib`, and is recommended for schemes that don't make a difference between Python and extension modules.)

For example, say you're installing a module distribution to your home directory under Unix—but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the `--install-scripts` option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home

directory, in this case):

```
python setup.py install --home=~ --install-scripts=scrip
```

Another Unix example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the **`--install-scripts`** option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the “prefix scheme”, where the prefix is whatever your Python interpreter was installed with— `/usr/local/python` in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of *prefix*, rather than right in *prefix* itself. This is almost as easy as customizing the script installation directory—you just have to remember that there are two types of modules to worry about, Python and extension modules, which can conveniently be both controlled by one option:

```
python setup.py install --install-lib=Site
```

The specified installation directory is relative to *prefix*. Of course, you also have to ensure that this directory is in Python’s module search path, such as by putting a `.pth` file in a site directory (see [site](#)). See section [Modifying Python’s Search Path](#) to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under `python` in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~ \
```

```
--install-purelib=python/lib \
--install-platlib=python/lib.$PLAT \
--install-scripts=python/scripts \
--install-data=python/data
```

or, equivalently,

```
python setup.py install --home=~/.python \
--install-purelib=lib \
--install-platlib='lib.$PLAT' \
--install-scripts=scripts \
--install-data=data
```

`$PLAT` is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section [Distutils Configuration Files](#)):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are *not* equivalent if you supply a different installation base directory when you run the setup script. For

example,

```
python setup.py install --install-base=/tmp
```

would install pure modules to `/tmp/python/lib` in the first case, and to `/tmp/lib` in the second case. (For the second case, you probably want to supply an installation base of `/tmp/python`.)

You probably noticed the use of `$HOME` and `$PLAT` in the sample configuration file input. These are Distutils configuration variables, which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as `$PLAT`. (And of course, on systems that don't have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section [Distutils Configuration Files](#) for details.

### Note

When a [virtual environment](#) is activated, any options that change the installation path will be ignored from all distutils configuration files to prevent inadvertently installing projects outside of the virtual environment.

## Modifying Python's Search Path

When the Python interpreter executes an `import` statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the `sys` module and printing the value of `sys.path`.

```
$ python
```

```
Python 2.2 (#11, Oct 3 2002, 13:31:27)
```

```
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux
```

```
Type "help", "copyright", "credits" or "license" for more
```

```
>>> import sys
```

```
>>> sys.path
['', '/usr/local/lib/python2.3', '/usr/local/lib/python2.3/lib-tk', '/usr/local/lib/python2.3/site-packages']
>>>
```

The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `.../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `.../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the [site](#) module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```
import sys
sys.path.append('/www/python/')
```

However, if you reinstall the same major version of Python

(perhaps when upgrading from 2.2 to 2.2.2, for example) `site.py` will be overwritten by the stock version. You'd have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify `sys.path`. **PYTHONHOME** sets an alternate value for the prefix of the Python installation. For example, if **PYTHONHOME** is set to `/www/python`, the search path will be set to `['', '/www/python/lib/pythonX.Y/', '/www/python/lib/pythonX.Y/platform-linux2', ...]`.

The **PYTHONPATH** variable can be set to a list of paths that will be added to the beginning of `sys.path`. For example, if **PYTHONPATH** is set to `/www/python:/opt/py`, the search path will begin with `['/www/python', '/opt/py']`. (Note that directories must exist in order to be added to `sys.path`; the **site** module removes paths that don't exist.)

Finally, `sys.path` is just a regular Python list, so any Python application can modify it by adding or removing entries.

## Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

### Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and macOS, the three configuration files (in the order they are processed) are:

**Types of files and filename**

---

```
(1) systemx/lib/pythonver/distutils/distutils.cfg
(2) systemx\lib\pythonver\distutils\distutils.cfg
(3) systemx\lib\pythonver\distutils\pydistutils.cfg
(4) systemx\lib\pythonver\distutils\localp.cfg
```

---

And on Windows, the configuration files are:

### Notes on file and filename

```
(1) systemx\Lib\distutils\distutils.cfg
(2) systemx\lib\pythonver\distutils\distutils.cfg
(3) systemx\lib\pythonver\distutils\pydistutils.cfg
(4) systemx\lib\pythonver\distutils\localp.cfg
```

---

On all platforms, the “personal” file can be temporarily disabled by passing the `--no-user-cfg` option.

Notes:

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to `prefix/lib/python1.5/site-packages/distutils`, so the system configuration file should be put there under Python 1.5.2.
2. On Unix, if the **HOME** environment variable is not defined, the user’s home directory will be determined with the `getpwuid()` function from the standard `pwd` module. This is done by the `os.path.expanduser()` function used by Distutils.
3. I.e., in the current directory (usually the location of the setup script).
4. (See also note (1).) Under Python 1.6 and later, Python’s default “installation prefix” is `C:\Python`, so the system configuration file is normally `C:\Python\Lib\distutils\distutils.cfg`. Under Python 1.5.2, the default prefix was `C:\Program Files\Python`, and the Distutils were not part of the standard library—so the system configuration file would be `C:\Program Files\Python\distutils\distutils.cfg` in a standard Python 1.5.2 installation under Windows.
5. On Windows, if the **HOME** environment variable is not defined, **USERPROFILE** then **HOMEDRIVE** and **HOMEPATH** will be tried. This is done by the `os.path.expanduser()`

function used by Distutils.

## Syntax of config files

The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a `global` section for global options that affect every command. Each section consists of one option per line, specified as `option=value`.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the **build\*** commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the **build** command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run, the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the **--help** option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using **--help** without a command:

```
python setup.py --help
```

See also the “Reference” section of the “Distributing Python Modules” manual.

## Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

### Tweaking compiler/linker flags

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn’t been tested on your platform, or if you’re trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `Setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines

have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...]
```

Let's examine each of the fields in turn.

- *module* is the name of the extension module to be built, and should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.
- *sourcefile* is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- *cpparg* is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.
- *library* is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the `Setup` file and running `python setup.py build`. For example, if the module defined by the line

```
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If a compiler option requires an argument, you'll have to supply multiple `-Xcompiler` options; for example, to pass `-x c++` the `Setup` file would have to contain `-Xcompiler -x`

`-Xcompiler c++.`

Compiler flags can also be supplied through setting the `CFLAGS` environment variable. If set, the contents of `CFLAGS` will be added to the compiler flags specified in the `Setup` file.

## Using non-Microsoft compilers on Windows

### Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the Borland C++ compiler version 5.5. First you have to know that Borland's object file format (OMF) is different from the format used by the Python version you can download from the Python or ActiveState web site. (Python is built with Microsoft Visual C++, which uses COFF as the object file format.) For this reason you have to convert Python's library `python25.lib` into the Borland format. You can do this as follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file `python25.lib` is in the `Libs` directory of your Python installation. If your extension uses other libraries (zlib, ...) you have to convert them too.

The converted files have to reside in the same directories as the normal libraries.

How does Distutils manage to use these libraries with their changed names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn't find such a special library it uses the default name (`foo.lib`) [1](#)

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you

could specify this in your personal or system-wide configuration file for Distutils (see section [Distutils Configuration Files](#).)

## GNU C / Cygwin / MinGW

This section describes the necessary steps to use Distutils with the GNU C/C + + compilers in their Cygwin and MinGW distributions.  
**2** For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

Not all extensions can be built with MinGW or Cygwin, but many can. Extensions most likely to not work are those that use C + + or depend on Microsoft Visual C extensions.

To let Distutils compile your extension with Cygwin you have to type:

```
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode **3** or for MinGW type:

```
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider writing it in your personal or system-wide configuration file for Distutils (see section [Distutils Configuration Files](#).)

### Older Versions of Python and MinGW

The following instructions only apply if you're using a version of Python inferior to 2.4.1 with a MinGW inferior to 3.0.0 (with binutils-2.13.90-20030111-1).

These compilers require some special libraries. This task is more complex than for Borland's C++ , because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at <https://sourceforge.net/projects/mingw/files/MinGW/Extension/pexports/>).

```
pexports python25.dll >python25.def
```

The location of an installed `python25.dll` will depend on the installation options and the version and language of Windows. In a "just for me" installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.

Then you can create from these information an import library for gcc.

```
/cygwin/bin/dlltool --dllname python25.dll --def python2
```

The resulting library has to be placed in the same directory as `python25.lib`. (Should be the `libs` directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

**See also**

**Building Python modules on MS Windows platform with MinGW** [[https://old.zope.dev/Members/als/tips/win32\\_mingw\\_modules](https://old.zope.dev/Members/als/tips/win32_mingw_modules)]

Information about building the required libraries for the MinGW environment.

## Footnotes

1

This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

2

Check <https://www.sourceware.org/cygwin/> for more information

3

Then you have no POSIX emulation available, but you also don't need `cygwin1.dll`.

*Low-level threading API.*

## [a](#)

[abc](#)

*Abstract base classes according to :pep:`3119`.*

[aifc](#)

**Deprecated:** *Read and write audio files in AIFF or AIFC format.*

[argparse](#)

*Command-line option and argument parsing library.*

[array](#)

*Space efficient arrays of uniformly typed numeric values.*

[ast](#)

*Abstract Syntax Tree classes and manipulation.*

[asynchat](#)

**Deprecated:** *Support for asynchronous command/response protocols.*

`asyncio`  
`asyncore`

*Asynchronous I/O.*  
**Deprecated:** A base class for developing asynchronous socket handling services.

`atexit`

*Register and execute cleanup functions.*

`audioop`

**Deprecated:**  
*Manipulate raw audio data.*

## **b**

`base64`

*RFC 4648: Base16, Base32, Base64 Data Encodings; Base85 and Ascii85*

`bdb`

*Debugger framework.*

`binascii`

*Tools for converting between binary and various ASCII-encoded binary representations.*

`bisect`

*Array bisection algorithms for binary searching.*

`builtins`

*The module that provides the built-in namespace.*

`bz2`

*Interfaces for bzip2 compression and decompression.*

## **c**

`calendar`

*Functions for working with calendars, including some emulation of the Unix cal program.*

`cgi`

**Deprecated:** *Helpers for running Python scripts via the Common*

<code>cgitb</code>	Gateway Interface. <b>Deprecated:</b>
<code>chunk</code>	Configurable traceback handler for CGI scripts. <b>Deprecated:</b> Module to read IFF chunks.
<code>cmath</code>	Mathematical functions for complex numbers.
<code>cmd</code>	Build line-oriented command interpreters.
<code>code</code>	Facilities to implement read-eval-print loops.
<code>codecs</code>	Encode and decode data and streams.
<code>codeop</code>	Compile (possibly incomplete) Python code.
<code>collections</code>	Container datatypes
<code>collections.abc</code>	Abstract base classes for containers
<code>colorsys</code>	Conversion functions between RGB and other color systems.
<code>compileall</code>	Tools for byte-compiling all Python source files in a directory tree.
<code>concurrent</code>	Execute computations
<code>concurrent.futures</code>	concurrently using threads or processes.
<code>configparser</code>	Configuration file parser.
<code>contextlib</code>	Utilities for with-statement contexts.
<code>contextvars</code>	Context Variables
<code>copy</code>	Shallow and deep copy operations.
<code>copyreg</code>	Register pickle support functions.
<code>cProfile</code>	

<code>crypt</code> (Unix)	<b>Deprecated:</b> The <code>crypt()</code> function used to check Unix passwords.
<code>csv</code>	Write and read tabular data to and from delimited files.
<code>ctypes</code>	A foreign function library for Python.
<code>curses</code> (Unix)	An interface to the <code>curses</code> library, providing portable terminal handling.
<code>curses.ascii</code>	Constants and set-membership functions for ASCII characters.
<code>curses.panel</code>	A panel stack extension that adds depth to <code>curses</code> windows.
<code>curses.textpad</code>	Emacs-like input editing in a <code>curses</code> window.

## d

<code>dataclasses</code>	Generate special methods on user-defined classes.
<code>datetime</code>	Basic date and time types.
<code>dbm</code>	Interfaces to various Unix "database" formats.
<code>dbm.dumb</code>	Portable implementation of the simple DBM interface.
<code>dbm.gnu</code> (Unix)	GNU's reinterpretation of <code>dbm</code> .
<code>dbm.ndbm</code> (Unix)	The standard "database" interface, based on <code>ndbm</code> .
<code>decimal</code>	Implementation of the General Decimal

	Arithmetic Specification.
<code>difflib</code>	Helpers for computing differences between objects.
<code>dis</code>	Disassembler for Python bytecode.
<code>distutils</code>	Support for building and installing Python modules into an existing Python installation.
<code>distutils.archive_util</code>	Utility functions for creating archive files (tarballs, zip files, ...)
<code>distutils.bcppcompiler</code>	Abstract CCompiler class
<code>distutils.ccompiler</code>	
<code>distutils.cmd</code>	Provides the abstract base class :class:`~distutils.cmd.Command` This class is subclassed by the modules in the <code>distutils.command</code> subpackage. Contains one module
<code>distutils.command</code>	for each standard Distutils command.
<code>distutils.command.bdist</code>	Build a binary installer for a package
<code>distutils.command.bdist_dumb</code>	Build a "dumb" installer for a package
<code>distutils.command.bdist_rpm</code>	Build a "simple" archive of files
<code>distutils.command.py2exe</code>	Abstract base class for package builders
<code>distutils.command.py2exe</code>	Build a binary distribution as a Redhat RPM and SRPM
<code>distutils.command.py2exe</code>	Build all files of a package

	Build any C libraries in a package
<code>distutils.command.clib</code>	
	Build any extensions in a package
<code>distutils.command.ext_text</code>	
	Build the .py/.pyc files of a package
<code>distutils.command.py_compile</code>	
	Build the scripts of a package
<code>distutils.command.sdist_scripts</code>	
	Check the meta-data of a package
<code>distutils.command.check</code>	
	Clean a package build area
<code>distutils.command.clean</code>	
	Perform package configuration
<code>distutils.command.config</code>	
	Install a package
<code>distutils.command.install</code>	
	Install data files from a package
<code>distutils.command.install_data</code>	
	Install C/C++ header files from a package
<code>distutils.command.install_headers</code>	
	Install library files from a package
<code>distutils.command.install_lib</code>	
	Install script files from a package
<code>distutils.command.install_scripts</code>	
	Register a module with the Python Package Index
<code>distutils.command.register</code>	
	Build a source distribution
<code>distutils.command.sdist</code>	
<code>distutils.core</code>	The core Distutils functionality
 <code>distutils.cygwincompiler</code>	 Provides the debug flag for distutils
<code>distutils.debug</code>	Utility functions for simple dependency checking
<code>distutils.dep_util</code>	Utility functions for operating on directories
<code>distutils.dir_util</code>	

	and directory trees
<code>distutils.dist</code>	Provides the Distribution class, which represents the module distribution being built/installed/distributed
<code>distutils.errors</code>	Provides standard distutils exceptions
<code>distutils.extension</code>	Provides the Extension class, used to describe C/C++ extension modules in setup scripts
<code>distutils.fancy_getopt</code>	Additional getopt functionality
<code>distutils.file_util</code>	Utility functions for operating on single files
<code>distutils.filelist</code>	The FileList class, used for poking about the file system and building lists of files.
<code>distutils.log</code>	A simple logging mechanism, :pep:`282`-style
<code>distutils.msvccompiler</code>	Microsoft Compiler
<code>distutils.spawn</code>	Provides the spawn() function
<code>distutils.sysconfig</code>	Low-level access to configuration information of the Python interpreter.
<code>distutils.text_file</code>	Provides the TextFile class, a simple interface to text files
<code>distutils.unixcompiler</code>	UNIX C Compiler
<code>distutils.util</code>	Miscellaneous other utility functions
	Implements classes that

<code>distutils.version</code>	represent module version numbers.
<code>doctest</code>	Test pieces of code within docstrings.

## e

<code>email</code>	Package supporting the parsing, manipulating, and generating email messages.
<code>email.charset</code>	Character Sets Storing and Retrieving
<code>email.contentmanager</code>	Content from MIME Parts
<code>email.encoders</code>	Encoders for email message payloads.
<code>email.errors</code>	The exception classes used by the email package.
<code>email.generator</code>	Generate flat text email messages from a message structure.
<code>email.header</code>	Representing non-ASCII headers
<code>email.headerregistry</code>	Automatic Parsing of headers based on the field name
<code>email.iterators</code>	Iterate over a message object tree.
<code>email.message</code>	The base class representing email messages.
<code>email.mime</code>	Build MIME messages.
<code>email.parser</code>	Parse flat text email messages to produce a message object structure.
<code>email.policy</code>	Controlling the parsing and generating of messages

<code>email.utils</code>	Miscellaneous email package utilities.
<b>encodings</b>	
<code>encodings.idna</code>	Internationalized Domain Names implementation
<code>encodings.mbcs</code>	Windows ANSI codepage
<code>encodings.utf_8_sig</code>	UTF-8 codec with BOM signature
<code>ensurepip</code>	Bootstrapping the "pip" installer into an existing Python installation or virtual environment.
<code>enum</code>	Implementation of an enumeration class.
<code>errno</code>	Standard errno system symbols.

## f

<code>faulthandler</code>	Dump the Python traceback.
<code>fcntl</code> (Unix)	The <code>fcntl()</code> and <code>ioctl()</code> system calls.
<code>filecmp</code>	Compare files efficiently.
<code>fileinput</code>	Loop over standard input or a list of files.
<code>fnmatch</code>	Unix shell style filename pattern matching.
<code>fractions</code>	Rational numbers.
<code>ftplib</code>	FTP protocol client (requires sockets).
<code>functools</code>	Higher-order functions and operations on callable objects.

## g

<code>gc</code>	Interface to the cycle-
-----------------	-------------------------

	<i>detecting garbage collector.</i>
<b>getopt</b>	<i>Portable parser for command line options; support both short and long option names.</i>
<b>getpass</b>	<i>Portable reading of passwords and retrieval of the userid.</i>
<b>gettext</b>	<i>Multilingual internationalization services.</i>
<b>glob</b>	<i>Unix shell style pathname pattern expansion.</i>
<b>graphlib</b>	<i>Functionality to operate with graph-like structures</i>
<b>grp</b> (Unix)	<i>The group database (getgrnam() and friends).</i>
<b>gzip</b>	<i>Interfaces for gzip compression and decompression using file objects.</i>

## **h**

<b>hashlib</b>	<i>Secure hash and message digest algorithms.</i>
<b>heapq</b>	<i>Heap queue algorithm (a.k.a. priority queue).</i>
<b>hmac</b>	<i>Keyed-Hashing for Message Authentication (HMAC) implementation</i>
<b>html</b>	<i>Helpers for manipulating HTML.</i>
<b>html.entities</b>	<i>Definitions of HTML general entities.</i>

`html.parser`

A simple parser that can handle HTML and XHTML.

`http`

HTTP status codes and messages

`http.client`

HTTP and HTTPS protocol client (requires sockets).

`http.cookiejar`

Classes for automatic handling of HTTP cookies.

`http.cookies`

Support for HTTP state management (cookies).

`http.server`

HTTP server and request handlers.

## **i**

`idlelib`

Implementation package for the IDLE shell/editor.

`imaplib`

IMAP4 protocol client (requires sockets).

`imghdr`

**Deprecated:**

Determine the type of image contained in a file or byte stream.

`imp`

**Deprecated:** Access the implementation of the import statement.

`importlib`

The implementation of the import machinery.

`importlib.abc`

Abstract base classes related to import

Importers and path

`importlib.machinery`

hooks

The implementation of

`importlib.metadata`

the importlib metadata.

Package resource

`importlib.resources`

reading, opening, and access

	Abstract base classes
<code>importlib.resources</code>	for resources
<code>importlib.util</code>	Utility code for importers
<code>inspect</code>	Extract information and source code from live objects.
<code>io</code>	Core tools for working with streams.
<code>ipaddress</code>	IPv4/IPv6 manipulation library.
<code>itertools</code>	Functions creating iterators for efficient looping.

## j

<code>json</code>	Encode and decode the JSON format.
<code>json.tool</code>	A command line to validate and pretty-print JSON.

## k

<code>keyword</code>	Test whether a string is a keyword in Python.
----------------------	-----------------------------------------------

## l

<code>lib2to3</code>	The 2to3 library
<code>linecache</code>	Provides random access to individual lines from text files.
<code>locale</code>	Internationalization services.
<code>logging</code>	Flexible event logging system for applications.
<code>logging.config</code>	Configuration of the logging module.
<code>logging.handlers</code>	Handlers for the logging module.
<code>lzma</code>	A Python wrapper for

*the liblzma compression library.*

## **m**

<b>mailbox</b>	<i>Manipulate mailboxes in various formats</i>
<b>mailcap</b>	<b>Deprecated:</b> <i>Mailcap file handling.</i>
<b>marshal</b>	<i>Convert Python objects to streams of bytes and back (with different constraints).</i>
<b>math</b>	<i>Mathematical functions (sin() etc.).</i>
<b>mimetypes</b>	<i>Mapping of filename extensions to MIME types.</i>
<b>mmap</b>	<i>Interface to memory-mapped files for Unix and Windows.</i>
<b>modulefinder</b>	<i>Find modules used by a script.</i>
<b>msilib</b> (Windows)	<b>Deprecated:</b> <i>Creation of Microsoft Installer files, and CAB files.</i>
<b>msvcrt</b> (Windows)	<i>Miscellaneous useful routines from the MS VC++ runtime.</i>
<b>multiprocessing</b>	<i>Process-based parallelism.</i>
<b>multiprocessing.connection</b>	<i>API for dealing with sockets.</i>
<b>multiprocessing.dummy</b>	<i>Dumb wrapper around threading.</i>
<b>multiprocessing.managers</b>	<i>Share data between processes with shared objects.</i>
<b>multiprocessing.pool</b>	<i>Create pools of processes.</i>
<b>multiprocessing.popen</b>	<i>Provides shared</i>

`multiprocessing.shared_memory` memory for direct access across processes. Allocate ctypes objects from shared memory.

## n

`netrc` Loading of .netrc files.

`nis` (Unix) **Deprecated:** Interface to Sun's NIS (Yellow Pages) library.

`nntplib` **Deprecated:** NNTP protocol client (requires sockets).

`numbers` Numeric abstract base classes (Complex, Real, Integral, etc.).

## o

`operator` Functions corresponding to the standard operators.

`optparse` **Deprecated:** Command-line option parsing library.

`os` Miscellaneous operating system interfaces.

`os.path` Operations on pathnames.

`ossaudiodev` (Linux, FreeBSD) **Deprecated:** Access to OSS-compatible audio devices.

## p

`pathlib` Object-oriented filesystem paths

`pdb` The Python debugger for interactive interpreters.

`pickle` Convert Python objects to streams of bytes and

<code>pickletools</code>	back. Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful functions.
<code>pipes</code> (Unix)	<b>Deprecated:</b> A Python interface to Unix shell pipelines.
<code>pkgutil</code>	Utilities for the import system.
<code>platform</code>	Retrieves as much platform identifying data as possible.
<code>plistlib</code>	Generate and parse Apple plist files.
<code>poplib</code>	POP3 protocol client (requires sockets).
<code>posix</code> (Unix)	The most common POSIX system calls (normally used via module <code>os</code> ).
<code>pprint</code>	Data pretty printer.
<code>profile</code>	Python source profiler.
<code>pstats</code>	Statistics object for use with the profiler.
<code>pty</code> (Unix)	Pseudo-Terminal Handling for Unix.
<code>pwd</code> (Unix)	The password database ( <code>getpwnam()</code> and friends).
<code>py_compile</code>	Generate byte-code files from Python source files.
<code>pyclbr</code>	Supports information extraction for a Python module browser.
<code>pydoc</code>	Documentation generator and online

*help system.*

## **q**

**queue**

*A synchronized queue class.*

**quopri**

*Encode and decode files using the MIME quoted-printable encoding.*

## **r**

**random**

*Generate pseudo-random numbers with various common distributions.*

**re**

*Regular expression operations.*

**readline** (Unix)

*GNU readline support for Python.*

**reprlib**

*Alternate repr() implementation with size limits.*

**resource** (Unix)

*An interface to provide resource usage information on the current process.*

**rlcompleter**

*Python identifier completion, suitable for the GNU readline library.*

**runpy**

*Locate and run Python modules without importing them first.*

## **s**

**sched**

*General purpose event scheduler.*

**secrets**

*Generate secure random numbers for managing secrets.*

**select**

*Wait for I/O completion*

<code>selectors</code>	on multiple streams. High-level I/O multiplexing.
<code>shelve</code>	Python object persistence.
<code>shlex</code>	Simple lexical analysis for Unix shell-like languages.
<code>shutil</code>	High-level file operations, including copying.
<code>signal</code>	Set handlers for asynchronous events.
<code>site</code>	Module responsible for site-specific configuration.
<code>smtpd</code>	<b>Deprecated:</b> A SMTP server implementation in Python.
<code>smtplib</code>	SMTP protocol client (requires sockets).
<code>sndhdr</code>	<b>Deprecated:</b> Determine type of a sound file.
<code>socket</code>	Low-level networking interface.
<code>socketserver</code>	A framework for network servers.
<code>spwd</code> (Unix)	<b>Deprecated:</b> The shadow password database ( <code>getspnam()</code> and friends).
<code>sqlite3</code>	A DB-API 2.0 implementation using SQLite 3.x.
<code>ssl</code>	TLS/SSL wrapper for socket objects
<code>stat</code>	Utilities for interpreting the results of <code>os.stat()</code> , <code>os.lstat()</code> and <code>os.fstat()</code> .

<b>statistics</b>	<i>Mathematical statistics functions</i>
<b>string</b>	<i>Common string operations.</i>
<b>stringprep</b>	<i>String preparation, as per RFC 3453</i>
<b>struct</b>	<i>Interpret bytes as packed binary data.</i>
<b>subprocess</b>	<i>Subprocess management.</i>
<b>sunau</b>	<b>Deprecated:</b> <i>Provide an interface to the Sun AU sound format.</i>
<b>symtable</b>	<i>Interface to the compiler's internal symbol tables.</i>
<b>sys</b>	<i>Access system-specific parameters and functions.</i>
<b>sysconfig</b>	<i>Python's configuration information</i>
<b>syslog (Unix)</b>	<i>An interface to the Unix syslog library routines.</i>

## **t**

<b>tabnanny</b>	<i>Tool for detecting white space related problems in Python source files in a directory tree.</i>
<b>tarfile</b>	<i>Read and write tar-format archive files.</i>
<b>telnetlib</b>	<b>Deprecated:</b> <i>Telnet client class.</i>
<b>tempfile</b>	<i>Generate temporary files and directories.</i>
<b>termios (Unix)</b>	<i>POSIX style tty control.</i>
<b>test</b>	<i>Regression tests package containing the testing suite for Python.</i>
<b>test.support</b>	<i>Support for Python's</i>

	regression test suite.
	Support tools for testing
<code>test.support.bytescode</code>	correct byte code generation.
	Support for import tests.
<code>test.support.import_helper</code>	
	Support for os tests.
<code>test.support.os_helper</code>	
	Support for Python's
<code>test.support.script_helper</code>	script execution tests.
	Support for socket tests.
<code>test.support.socket_helper</code>	
	Support for threading
<code>test.support.threading_helper</code>	tests.
	Support for warnings
<code>test.support.warnings_helper</code>	tests.
<code>textwrap</code>	Text wrapping and filling
<code>threading</code>	Thread-based parallelism.
<code>time</code>	Time access and conversions.
<code>timeit</code>	Measure the execution time of small code snippets.
<code>tkinter</code>	Interface to Tcl/Tk for graphical user interfaces
	Color choosing dialog
<code>tkinter.colorchooser</code>	
<code>(Tk)</code>	
	Tkinter base class for
<code>tkinter.commondialog</code>	dialogs
<code>(Tk)</code>	
<code>tkinter.dnd</code>	Tkinter drag-and-drop interface
<code>(Tk)</code>	
	Dialog classes for file
<code>tkinter.filedialog</code>	selection
<code>(Tk)</code>	
<code>tkinter.font</code>	Tkinter font-wrapping class
<code>(Tk)</code>	

<code>tkinter.messagebox</code> (Tk)	Various types of alert dialogs
<code>tkinter.scrolledtext</code> (Tk)	Text widget with a vertical scroll bar.
<code>tkinter.simpledialog</code> (Tk)	Simple dialog windows
<code>tkinter.tix</code>	Tk Extension Widgets for Tkinter
<code>tkinter.ttk</code>	Tk themed widget set
<code>token</code>	Constants representing terminal nodes of the parse tree.
<code>tokenize</code>	Lexical scanner for Python source code.
<code>tomllib</code>	Parse TOML files.
<code>trace</code>	Trace or track Python statement execution.
<code>traceback</code>	Print or retrieve a stack traceback.
<code>tracemalloc</code>	Trace memory allocations.
<code>tty</code> (Unix)	Utility functions that perform common terminal control operations.
<code>turtle</code>	An educational framework for simple graphics applications
<code>turtledemo</code>	A viewer for example turtle scripts
<code>types</code>	Names for built-in types.
<code>typing</code>	Support for type hints (see :pep:`484`).

## u

<code>unicodedata</code>	Access the Unicode
--------------------------	--------------------

<code>unittest</code>	Database. Unit testing framework for Python.
<code>unittest.mock</code>	Mock object library.
<code>urllib</code>	
<code>urllib.error</code>	Exception classes raised by <code>urllib.request</code> .
<code>urllib.parse</code>	Parse URLs into or assemble them from components.
<code>urllib.request</code>	Extensible library for opening URLs.
<code>urllib.response</code>	Response classes used by <code>urllib</code> .
<code>urllib.robotparser</code>	Load a <code>robots.txt</code> file and answer questions about fetchability of other URLs.
<code>uu</code>	<b>Deprecated:</b> Encode and decode files in uuencode format.
<code>uuid</code>	UUID objects (universally unique identifiers) according to RFC 4122

## V

<code>venv</code>	Creation of virtual environments.
-------------------	-----------------------------------

## W

<code>warnings</code>	Issue warning messages and control their disposition.
<code>wave</code>	Provide an interface to the WAV sound format.
<code>weakref</code>	Support for weak references and weak dictionaries.
<code>webbrowser</code>	Easy-to-use controller

	<i>for web browsers.</i>
<code>winreg</code> (Windows)	<i>Routines and objects for manipulating the Windows registry.</i>
<code>winsound</code> (Windows)	<i>Access to the sound-playing machinery for Windows.</i>
<code>wsgiref</code>	<i>WSGI Utilities and Reference Implementation.</i>
<code>wsgiref.handlers</code>	<i>WSGI server/gateway base classes.</i>
<code>wsgiref.headers</code>	<i>WSGI response header tools.</i>
<code>wsgiref.simple_server</code>	<i>A simple WSGI HTTP server.</i>
<code>wsgiref.types</code>	<i>WSGI types for static type checking</i>
<code>wsgiref.util</code>	<i>WSGI environment utilities.</i>
	<i>WSGI conformance checker.</i>
<code>wsgiref.validate</code>	

## X

<code>xdrlib</code>	<b>Deprecated:</b> <i>Encoders and decoders for the External Data Representation (XDR).</i>
<code>xml</code>	<i>Package containing XML processing modules</i>
<code>xml.dom</code>	<i>Document Object Model API for Python.</i>
<code>xml.dom.minidom</code>	<i>Minimal Document Object Model (DOM) implementation.</i>
<code>xml.dom.pulldom</code>	<i>Support for building partial DOM trees from SAX events.</i>
	<i>Implementation of the</i>

<code>xml.etree.ElementTree</code>	<i>ElementTree API. An interface to the</i>
<code>xml.parsers.expat</code>	<i>Expat non-validating XML parser.</i>
<code>xml.parsers.expat.errors</code>	
<code>xml.parsers.expat.model</code>	
<code>xml.sax</code>	<i>Package containing SAX2 base classes and convenience functions. Base classes for SAX event handlers.</i>
<code>xml.sax.handler</code>	<i>Convenience functions and classes for use with SAX.</i>
<code>xml.sax.saxutils</code>	<i>Interface which SAX- compliant XML parsers must implement.</i>
<code>xmlrpc</code>	
<code>xmlrpc.client</code>	<i>XML-RPC client access.</i>
<code>xmlrpc.server</code>	<i>Basic XML-RPC server implementations.</i>

## **z**

<code>zipapp</code>	<i>Manage executable Python zip archives</i>
<code>zipfile</code>	<i>Read and write ZIP- format archive files.</i>
<code>zipimport</code>	<i>Support for importing Python modules from ZIP archives.</i>
<code>zlib</code>	<i>Low-level interface to compression and decompression routines compatible with gzip.</i>
<code>zoneinfo</code>	<i>IANA time zone support</i>

# Download Python 3.11.3 Documentation

**Last updated on: May 01, 2023.**

To download an archive containing all the documents for this version of Python in one of various formats, follow one of links in this table.

Format	Packed as .zip	Packed as .tar.bz2
PDF (US-Letter paper size)	<a href="#">Download</a> (ca. 13 MiB)	<a href="#">Download</a> (ca. 13 MiB)
PDF (A4 paper size)	<a href="#">Download</a> (ca. 13 MiB)	<a href="#">Download</a> (ca. 13 MiB)
HTML	<a href="#">Download</a> (ca. 9 MiB)	<a href="#">Download</a> (ca. 6 MiB)
Plain Text	<a href="#">Download</a> (ca. 3 MiB)	<a href="#">Download</a> (ca. 2 MiB)
EPUB	<a href="#">Download</a> (ca. 5 MiB)	

These archives contain all the content in the documentation.

## Unpacking

Unix users should download the .tar.bz2 archives; these are bzipipped tar archives and can be handled in the usual way using tar and the bzip2 program. The [InfoZIP](#) unzip program can be used to handle the ZIP archives if desired. The .tar.bz2 archives provide the best compression and fastest download times.

Windows users can use the ZIP archives since those are customary on that platform. These are created on Unix using the InfoZIP zip program.

## Problems

If you have comments or suggestions for the Python documentation, please send email to [docs@python.org](mailto:docs@python.org).

# Python 3.11.3 documentation

Welcome! This is the official documentation for Python 3.11.3.

## Parts of the documentation:

### Installing Python Modules

installing from the "Python Packaging 1210" & other sources

### Distributing Python Modules

publishing modules for installation by others

### Extending and Embedding

helping you write your C/C++ extensions

### Python C Reference

describes Python C API and programming

### Python Setup and Usage

frequently asked questions (on platforms!)

### Python HOWTOs

in-depth documents on specific topics

## Indices and tables:

### Search Page

search the documentation

### Complete Table of Contents

list of all sections, classes, subsections

### Glossary

the most important terms explained

## Meta information:

### Reporting bugs and giving feedback

[Copyrighting to Docs](#)  
[About the documentation](#)

## Note

This document is being retained solely until the `setuptools` documentation at <https://setuptools.readthedocs.io/en/latest/setuptools.html> independently covers all of the relevant information currently included here.

# The Python Package Index (PyPI)

The [Python Package Index \(PyPI\)](https://pypi.org) [https://pypi.org] stores metadata describing distributions packaged with distutils and other publishing tools, as well the distribution archives themselves.

References to up to date PyPI documentation can be found at [Reading the Python Packaging User Guide](#).

# Uploading Packages to the Package Index

References to up to date PyPI documentation can be found at [Reading the Python Packaging User Guide](#).
